Notes:

Price Level, FY-07

Unit Cost based on Historical Data, Recent Pricing, & Estimator's Judgment

Cost Estimate Type is PROGRAMMING & PLANNING "Parametric Type"

Quantities listed within the Estimate represent Major Elements of the Project

Structural Removal Cost includes minor Site Restoration (filling septic tanks, removal outside structures, pavements & utilities)

Utility Removal Cost includes, sewer, storm drain, water, gas, power, cable, phone, traffic signaling

Estimate Excl Operational & Maintenance Cost

Project Escalation

Relocations, Environment, HTRW & Real Estate Cost (except PCA)

Historical Preservation

Asbestos Removal during Structure Removal

PROJECT:	**Mississippi Coastal Improvements Program "MsCIP"**	ITEM NO.	DATE	(revised) 25-Jul-08
LOCATION:	**Mississippi**	SHEET NO. 1	OF	1
		PREPARED: Joseph H. Ellsworth	CHECKED:	Gary A. Payton
WORK ITEM:	***Summary***	BASIS of ESTIMATE: Info furnished per Project Delivery Team		
		FILE NAME:		mscip-comprehensive-study-compbined-cost-est-25jul08.xls

DESCRIPTION	ESTIMATED AMOUNT

ENVIRONMENTAL RESTORATION

Hancock County **Admiral Island**

0.5 METER PLANTINGS WITH FILL	**$ 26,300,000**
1.0 METER PLANTINGS WITH FILL	**$ 23,800,000**
2.0 METER PLANTINGS WITH FILL	**$ 22,500,000**
0.5 METER PLANTINGS WITHOUT FILL	**$ 26,300,000**
1.0 METER PLANTINGS WITHOUT FILL	**$ 23,700,000**
2.0 METER PLANTINGS WITHOUT FILL	**$ 22,400,000**

Notes:

Price Level, Oct 07

Unit Cost based on Historical Data, Recent Pricing, & Estimator's Judgment

Cost Estimate Type is PROGRAMMING & PLANNING "Parametric Type"

Quantities listed within the Estimate represent Major Elements of the Project

Structural Removal Cost included in nonstructural estimates

Utility Removal Cost includes, sewer, storm drain, water, gas, power, cable, phone, traffic signaling

Estimate Exclud Operational & Maintenance Cost

Project Escalation

Relocations, Environment, HTRW & Real Estate Cost (except PCA)

Historical Preservation

DESCRIPTION			ESTIMATED AMOUNT
ENVIRONMENTAL RESTORATION			
Harrison County	**Turkey Creek**	**North and South of Railroad**	**$ 7,600,000**
Harrison County	**Turkey Creek**	**North of Railroad**	**$1,900,000**
Harrison County	**Turkey Creek**	**South of Railroad**	**$5,900,000**

Notes:

Price Level, Oct 07
Unit Cost based on Historical Data, Recent Pricing, & Estimator's Judgment
Cost Estimate Type is PROGRAMMING & PLANNING "Parametric Type"
Quantities listed within the Estimate represent Major Elements of the Project
Structural Removal Cost includes minor Site Restoration (filling septic tanks, removal outside structures, pavements & utilities)
Utility Removal Cost includes, sewer, storm drain, water, gas, power, cable, phone, traffic signaling
Estimate Excluc Operational & Maintenance Cost
Project Escalation
Relocations, Environment, HTRW & Real Estate Cost (except PCA)
Historical Preservation
Asbestos Removal during Structure Removal
01 Account, Lands & Damage (land + admin + 25% contingency) in all options at $736,178.

DATE 25-Jul-08

DESCRIPTION		ESTIMATED AMOUNT
ENVIRONMENTAL RESTORATION		
Jackson County Replanting Effort	**Bayou Cumbest Area 30**	
0.5 METER PLANTINGS WITH FILL	(monitoring only 5 yrs @ $7,000)	$35,000
1.0 METER PLANTINGS WITH FILL		$ 2,400,000
2.0 METER PLANTINGS WITH FILL		$ 2,400,000
0.5 METER PLANTINGS WITHOUT FILL	(monitoring only 5 yrs @ $7,000)	$35,000
1.0 METER PLANTINGS WITHOUT FILL		$ 2,400,000
2.0 METER PLANTINGS WITHOUT FILL		$ 2,400,000

****THESE REPLANTING COSTS WILL OCCUR IN YEARS 3 AND 5 OF THE PERIOD OF ANALYSIS.***

Notes:

Price Level, Oct 07
Unit Cost based on Historical Data, Recent Pricing, & Estimator's Judgment
Cost Estimate Type is PROGRAMMING & PLANNING "Parametric Type"
Quantities listed within the Estimate represent Major Elements of the Project
Estimate Excludes Project Escalation

COST APPENDIX

PART 2

PART 2

RECOMMENDED ALTERNATIVES

Part 2 of the Cost Appendix contains updated cost estimates for the recommended alternatives in the Comprehensive Plan and Integrated Programmatic Environmental Impact Statement. Selected structural and environmental options included in the Engineering Appendix and Part 1 of the Cost Appendix were used as the basis for the selected alternatives. All recommended alternatives other than the Homeowners Assistance Relocation Program (HARP) have Total Projects Cost Summaries included herein. Part 2 also includes an Escalation Derivations Chart used for the updated costs, Gnatt charts with brief project descriptions, and results of a Cost Risk Analysis completed for the Barrier Island Restoration Plan. The HARP is a program based on purchase of 1800 to 2000 properties in coastal Mississippi out of 17,000 that were identified as being in high hazard areas. These 17,000 properties were identified in the "Preliminary Estimate of Project Cost for the Floodproofing of Residential Structures" and is based on a price level equivalent to 1 October, 2007. This document is also included. The costs for the structural and environmental alternatives were completed by Mobile District and the costs for the nonstructural alternatives were completed by Huntington District.

Some quantity of high quality sand may be available in the old channel alignment at the west end of West Ship Island. If there is deemed a sufficient quantity of sand to use from this area, this sand could be pumped to areas on the northern shore of West Ship Island that has been included in the areas to be filled near Fort Massachusetts.

West and East Ship Island also have two major historic sites that are in danger from the continuing erosion of the barrier islands. The presence of these historic sites led to the inclusion of the barrier islands off the coast of Mississippi as a National Seashore. Current studies by the Corps indicate that restoring the two islands to a single island, pre-Camille condition may prevent the rapid erosion of the beaches that is now occurring at these sites and aid in the reduction of erosion that is endangering Historic Fort Massachusetts on West Ship Island. The placement of sand on the northern side of West Ship Island under the filling of Camille Cut will be considered a priority to provide protection to the Fort as early as possible in the course of this work. The addition of sheet pile for minimizing erosional loss of the sand during placement will be allowed as long as the sheet pile is removed. It can be assumed that a 2000 foot running length will be used as the fill progresses across the open pass. The transfer of heavy equipment from barges to both of the islands can be done in selected locations where deeper water is close to the existing shorelines.

The pre-Camille footprint of Ship Island was obtained from historical records and this data showed that the island was breached during Hurricane Camille in 1969 forming two separate islands as mentioned above. This breach had been partially filled with a sand spit extending westward from East Ship Island when Hurricane Katrina again opened the breach in 2005. As happened during Hurricane Camille, the new breach was formed leaving two islands with approximately three miles of open water between the remaining portions. West Ship Island has been experiencing severe erosion in some areas because of the loss of sand in the system from the ebb tidal flows through the breach. East Ship Island is also losing land mass as the sand in its system migrates into the breach area. Currents studies (USGS, 2007 and Rosati, 2007) indicate that West and East Ship will probably not recover from their current severely eroded state.

The first step in the barrier restoration process would be to fill the three mile breach in Ship Island, Camille Cut, to a 1000-foot width and a height that would require approximately 13-million cubic yards of sand including loss during placement and the re-nourishment of some erosion along the northern shore. The other two measures would be to add sand into the littoral system with about 5-million cubic yards going into the area east of East Ship Island and the rest (4-million cubic yards) going to the area east of Petit Bois Island. Placing more sand at Ship Island is assumed because of the accelerated erosion that has taken place there. The quantities of material assumed for the littoral placements would be subject to change after additional sediment transport modeling if this modeling indicates this adjustment.

West Ship has migrated westward along the littoral drift zone with the western end of the island now terminating against the deep-water, Gulfport navigation channel that prevents further drift. Studies (Rosati, 2007) have confirmed that West Ship Island is the last active island system in the littoral zone that originates in northwest Florida. The same type of land loss exists for Petit Bois Island where the east end is migrating westward and the western end is now terminated against the Pascagoula navigation channel. Records indicate that over 22 million cubic yards of sediment have been removed for maintenance from the Pascagoula Channel since it was created. This quantity of sand was used as the basis of adding sand back into the littoral system since, theoretically, this sand would have continued its transport

Date	Author	Note
	Joseph H. Ellsworth	The addition of sand into the littoral system on the eastern ends of East Ship and Petit Bois Islands will provide a sediment source for the islands and help mitigate any affects from the maintenance of the navigation channels. The additional sediment transport modeling will include modeling to predict the optimal location for the placement of sand into the littoral zone near the islands to provide a source of sand for the natural healing on the breach. The quantity of sand required for these options are considerably less than the total restoration of the islands, but still substantial. To fill the breach, the sand would have strict requirements on color, grain size, and roundness. In discussions with the USGS, a potential source of sand was identified at St. Bernard Shoals which is a submerged chain of barrier islands approximately 45 miles south of the Mississippi barrier islands. Both quality and quantity are assumed to be available, but further investigations are required to verify the source. Activity from oil and gas production in the local area must also be considered. As described above approximately 13,000,000 cubic yards of the high quality sand are needed to fill the breach. An additional 5,000,000 cubic yards of sand is being proposed for placement into the littoral zone east of East Ship Island. This sand would still have physical compatibility characteristics to the sand in the littoral system that must be considered. The last measure of the plan would be to add approximately 4,000,000 cubic yards of compatible sand into the littoral zone east of Petit Bois Island. The source of this sand is also proposed to be from the St. Bernard Shoals. The placement of sand to fill Camille Cut and the two large littoral zone placements are planned as one-time events to restore some of the islands land surface that may have been lost to erosion from mans past activities or from mass erosion during storm events. This decision was based on an agreement with the NPS that allows them to mitigate ay damage from mans activities or to perform necessary means to preserve historic sites. This agreement has a positive aspect to MsCIP with the replacement of sand that has been lost from the littoral system. This sand addition will extend the life of the islands and the closure of Camille Cut will help maintain the boundaries of the estuary. It is understandably difficult to quantify either of these sand loss causes because the barrier islands themselves are dynamic systems that are undergoing constant change. The detailed cost estimate will be based as follows: Barrier Island Comprehensive Plan Cost Items Contract 1: Fill Camille Cut by Direct Placement – 13,000,000 cy (10,200,000 cy measured in place in place with estimated 30% loss during handling) placed to create a 1,000 foot wide fill for the existing breach with 60-foot wide swath of plantings along both shores (477,500 total plants). Source of sand borrow from St. Bernard Shoals. Assume using 2,000 running feet of sheet pile to add placement. See LOD-1, Option G in the Engineering Appendix. Award Jan 2010 Period of Performance – 4 years Contract 2 Little Dog Keys Pass Littoral Placement – 5,000,000 cy (measured in the dredge hopper) placed in an area approximately 1.5 square miles in up to 5 foot lift. Source of sand borrow from St. Bernard Shoals. See LOD-1, Option C1 in the Engineering Appendix. Award Jan 2011 Period of Performance – 2 years Contract 3 Petit Bois Island Littoral Placement – 4,000,000 cy (measured on the barges) placed in one area of approximately 2 square miles in up to a 3 foot lift. Source of sand borrow from St. Bernard Shoals. See LOD-1, Option C2 in the Engineering Appendix for quantities, but the source area has changed as indicated above. Award Jan 2012 Period of Performance – 2 years
7/28/2008	Joseph H. Ellsworth	BASIS of COST ESTIMATE and RATIONALE Feasibility Estimate is based on Historical Data, Recent Pricing, and Estimator's Judgment. Estimate is structured and priced as a general prime dredging contractor. Anticipated bidding conditions and construction duration with reasonable schedules are considered Normal. Unit cost as shown in estimate, are fair and reasonable rates based on fair market value. Estimates represent Current Contract Cost (price level Aug 08).

Date	Author	Note

Project Life is assumed as 50 years in Cost Estimate.

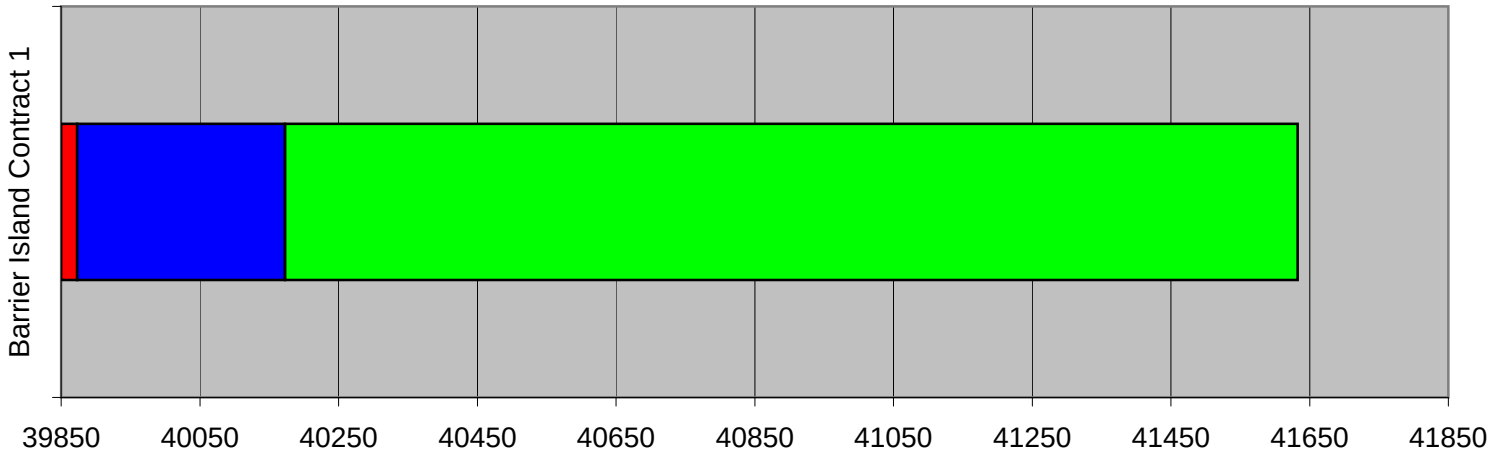
17 Feature Account, Beach Replenishment (Barrier Islands) - was developed using CEDEP. Reference CEDEP for Cost Derivation.

30 Feature Account, Planning, Engineering & Design was developed and assigned at 4% by the PDT. This is the percentage that has historically been used for these types of civil works projects. Eight percent was used in the Interim MsCIP projects which was reviewed and approved and included in the Chief's Report.

31 Feature Account, Construction Management was developed and assigned at 6% by the PDT. This is the percentage that has historically been used for these types of civil works projects. Six percent was used in the Interim MsCIP projects which was reviewed & approved and included in the Chief's Report.

Contingency was jointly developed and assigned by the Project Delivery Team. The Contingency percentage at 33% (80% confidence level) weighted average reflects the possibility of changes in quantity estimates and unknowns associated with the unit price. The contingency factor used is different for each contract. A risk analysis was performed by Walla Walla District for each contract within project. A risk analysis report is included in maint report.

Markups for subcontractors are included in the unit prices and include such items as field overheads, home office expenses, profit, bond and insurance.



Mobilization & Demobilization are derived within the CEDEP estimates.

Unit Prices, for such items as closure piling and planting is based on Historical Data, Recent Pricing, Estimator’s Judgment, and Cost derivation using MCACES / MII estimating systems.

			14.14
01 Contract 1 - Fill Camille Cut by Direct Placement	**13,000,000.00**	**CY**	**183,829,000**
(Note: SCOPE OF WORK Contract 1: Fill Camille Cut by Direct Placement – 13,000,000 cy (10,200,000 cy measured in place in place with estimated 30% loss during handling) placed to create a 1,000 foot wide fill for the existing breach with 60-foot wide swath of plantings along both shores (477,500 total plants). Source of sand borrow from St. Bernard Shoals. Assume using 2,000 running feet of sheet pile to add placement. See LOD-1, Option G in the Engineering Appendix. Award Jan 2010 Period of Performance – 4 years CONTRACT NO. 1 FILL CAMILLE CUT CONNECTING WEST AND EAST SHIP ISLANDS Work will commence January 2010. The work will be scheduled for 4 years. The material will be obtained by hopper dredge from the St. Bernard shoals some 45 miles to the south. The material will be transported to the -30 contour and pumped into the work area. Small dozer equipment will be required to shape the material above water. A template 1000 feet wide for the full length of the closure will be established and the Contractor shall be paid in increments completed placement. Approximately 3,250,000 c.y. of material will be placed each year. Sheet pile will be required to secure the end of a placement at the end of each year. Assume that you purchase and install 60,000 square feet of sheet pile at the end of year 1. At the start of year 2 you must recover the 60,000 square feet and store the material. Assume 10 percent or 6,000 square feet must be replaced. At the end of year 2, Install 60,000 square feet of sheet pile. At the beginning of year 3, recover 60,000 SF of sheet pile. Assume 10 percent or 6,000 SF of sheet pile must be replaced. At the end of year 3 install 60,000 SF of sheet pile. At the beginning of year 4 recover 60,000 SF of sheet pile and salvage or discard. Summary---- Purchase 72,000 SF of sheet pile. Install 180,000 SF of sheet pile. Recover 180,000 SF of sheet pile. Fill quantity is 13,000,000 c.y. Plant 477,500 sea oats on the created surface Assume 1major mob and demob and 3 intermediate mob and demob.)

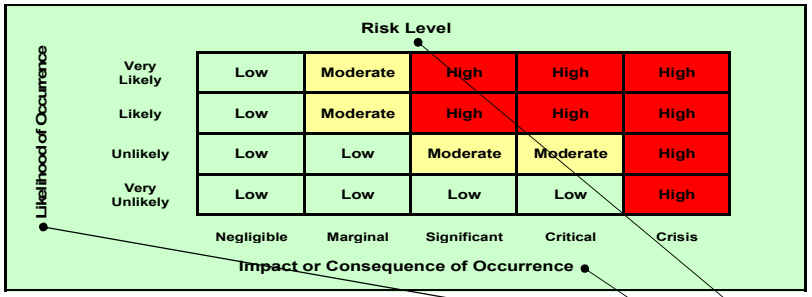
Contract 1 of the Barrier Islands consists of direct placement of approximately 13,000,000 CY of sand to fill the breach in Ship Island known as Camille Cut and along the north shore of the existing land surface. All of the constructed beach will be planted with a 60-foot wide swath of sea oats. The required sand will be obtained from St. Bernard Shoals which is located appromately 45 miles south of the island where the water depth is about 60-feet. The sand will be placed by pump-off from offshore. Design will start in March , 2009, award will be in Janurary 2010, and completion will be in December, 2011.

Design



Period of Performance

Contract 2 of the Barrier Islands consists of placement of approximately 5,000,000 CY of sand into the littoral zone between Ship and Horn Island. The sand will be spread over a designated into open water. The required sand will be obtained from St. Bernard Shoals which is located appromately 45 miles south of the island where the water depth is about 60-feet. The sand will be placed by pump-off from offshore. Design will start in March , 2009, award will be in Janurary 2011, and completion will be in January, 2012.

MsCIP Barrier Island Restoration - PDT Risk Register (Draft)

Risk No.	Risk/Opportunity Event	Discussion and Concerns	Project Cost				Project Schedule				Variance Distribution	Correlation to Other(s)	Responsibility/POC	Affected Project Component	Project Implications
			Likelihood*	Impact*	Risk Level*	Rough Order Impact ($)	Likelihood*	Impact*	Risk Level*	Rough Order Impact (mo)					
	Internal Risks (Internal Risk Items are those that are generated, caused, or controlled within the PDT's sphere of influence.)														
I-1	Project competing with other programs	Project competing with other programs (CG funds) in other geographic locations, such as New Orleans, East Coast, and elsewhere.	Very Likely	Critical	High		Very Likely	Critical	High		Uniform	I-2, E-3, E-4	Project Mgr.	Project Schedule	Cost & Schedule
I-2	Project Schedule in question	Assumed funding received in emergency stimulus supplemental. However, still have 1.5 years before actual work can begin. Could be affected by COE receipt of funding as well at KTR's ability and availability to execute.	Likely	Significant	High		Likely	Critical	High		Triangular	I-1, I-6, I-16, E-4	Project Mgr.	Project Schedule	Cost & Schedule
I-3	Pressure to deliver project on accelerated schedule	Project is critical -- sponsor pressure to complete as soon as possible.	Likely	Marginal	Moderate		Likely	Marginal	Moderate		Triangular		Project Mgr.	Project Schedule	Cost & Schedule
I-4	Acquisition Strategy	PDT does not have a finalized strategy on contract type (IDIQ, rental-hour, etc.). However, confident that it will go full and open, sealed bid.	Unlikely	Marginal	Low		Unlikely	Marginal	Low		Uniform	I-6	Contracting	Project Cost & Schedule	Cost & Schedule
I-5	Validation of borrow sources (quality of material)	Still awaiting final sample results, indicating quality and suitability of material at all sites.	Unlikely	Significant	Moderate		Unlikely	Significant	Moderate		Triangular	I-6	Civil Design	Contract Cost & Schedule	Cost & Schedule
I-6	Identification of closer sources of material	Possible source 4-5 miles offshore. Otherwise, will have to rely on source that is significantly further away (45+ miles).	Likely	Significant	High		Likely	Significant	High		Triangular	I-2, I-4, I-5, I-12, I-16, I-17, E-1	Civil Design	Contract Cost & Schedule	Cost & Schedule
I-7	In-water pipeline conflicts	There are existing underground/in-water pipelines in the area. They will have to be mapped by geo-hazard survey. Could present challenges to KTR (depth concerns, esp. as related to weather).	Unlikely	Significant	Moderate		Unlikely	Significant	Moderate		Triangular	I-9	Civil Design	Contract Cost & Schedule	Cost & Schedule
I-8	Environmental work windows (turtle nesting periods)	Rigid windows established in the region that forbid operations during certain periods of the year.	Unlikely	Marginal	Low		Unlikely	Marginal	Low		Triangular		Planning/Environmental	Contract Cost & Schedule	Cost & Schedule
I-9	Incomplete data and surveys	The plan is currently based on worst case scenario, in terms of the source locations. More data could identify more favorable scenarios.	Likely	Significant	High		Likely	Significant	High		Triangular	I-7	Civil Design	Contract Cost & Schedule	Cost & Schedule
I-10	Historical sites	NPS owned and operated historical sites, located on Ship Islands (Contract 1). Design of project has taken into consideration to preserve these resources.	Very Unlikely	Significant	Low		Very Unlikely	Significant	Low		Triangular		Planning/Archaeology	Contract Cost & Schedule	Cost & Schedule
I-11	Endangered species	Gulf sturgeon and piping plover in the area. COE has begun consultation regarding issues. Design has accounted for issues to mitigate these concerns.	Unlikely	Significant	Moderate		Unlikely	Significant	Moderate		Triangular		Planning/Environmental	Contract Cost & Schedule	Cost & Schedule
I-12	Supplemental NEPA document	Will draft a supplemental NEPA document after borrow sites are identified.	Unlikely	Marginal	Low		Unlikely	Marginal	Low		Triangular	I-6	Project Mgr.	Contract Cost & Schedule	Cost & Schedule

I-13	Level of review assumed	PDT has already anticipated HQ level review required. Therefore, risk of unanticipated higher level reviews is mitigated.	Likely	Negligible	Low		Likely	Negligible	Low		Triangular		Project Mgr.	Project Schedule	Schedule
I-14	Sites in National Parks	Sites are in National Parks, but NPS is a partner in this program.	Very Unlikely	Negligible	Low		Very Unlikely	Negligible	Low		Triangular		Project Mgr.	Contract Cost & Schedule	Cost & Schedule
I-15	EIS not complete	EIS not complete. Also, there are other studies that have not been completed regarding geotechnical data and benthic studies.	Very Likely	Negligible	Low		Very Likely	Negligible	Low		Triangular		Project Mgr.	Project Schedule	Schedule
I-16	Construction schedules	Unforeseen or competing events (such as storms or emergencies) could impact schedule for contractors to complete the work as planned and schedules.	Likely	Marginal	Moderate		Likely	Significant	High		Triangular	I-6, I-17	Cost Engr.	Contract Schedule	Schedule
I-17	Dredge methodology	Estimate currently assumes that the work under Contract 1 will be performed by the Glen Edwards. The number of dredges and crew would increase significantly if this is not true.	Likely	Significant	High		Likely	Significant	High		Uniform	I-6, I-16, E-1	Cost Engr.	Contract Cost & Schedule	Cost & Schedule
	External Risks (External Risk Items are those that are generated, caused, or controlled exclusively outside the PDT's sphere of influence.)														
E-1	Limited number of contractors available to bid on Contract 1	Only large hopper dredge contractors would be available to bid on Contract 1, as currently configured.	Likely	Significant	High		Likely	Marginal	Moderate		Triangular	I-6, I-17, E-6	Cost Engr.	Contract Cost	Cost
E-2	Unusually severe weather	Risk of severe storms or hurricanes impacting the area.	Likely	Marginal	Moderate		Likely	Significant	High		Uniform		N/A	Contract Schedule	Schedule
E-3	Inadequate incremental (or full) funding	Risk of not receiving planned funding stream amounts or in a timely fashion.	Likely	Marginal	Moderate		Likely	Significant	High		Uniform	I-1, E-4	Project Mgr.	Project Cost & Schedule	Cost & Schedule
E-4	HQ-Level priority changes	Risk of program being tabled or postponed in favor of other programs.	Unlikely	Significant	Moderate		Unlikely	Significant	Moderate		Uniform	I-1, I-2	Project Mgr.	Project Cost & Schedule	Cost & Schedule
E-5	Fuel prices	Risk of continued high or exorbitant increased in fuel costs.	Likely	Significant	High		Likely	Negligible	Low		Triangular		Cost Engr.	Contract Cost	Cost
E-6	Availability of contractors/bid climate	Risk captures risk of competing programs and economic climate limiting competition for bidding on this program.	Unlikely	Significant	Moderate		Unlikely	Significant	Moderate		Uniform	E-1	Cost Engr.	Contract Cost & Schedule	Cost & Schedule

*Likelihood, Impact, and Risk Level to be verified through market research and analysis (conducted by cost engineer).

1. Risk/Opportunity identified with reference to the Risk Identification Checklist and through deliberation and study of the PDT.
2. Discussions and Concerns elaborates on Risk/Opportunity Events and includes any assumptions or findings (should contain information pertinent to eventual study and analysis of event's impact to project).
3. Likelihood is a measure of the probability of the event occurring -- **Very Unlikely**, **Unlikely**, **Moderately Likely**, **Likely**, **Very Likely.** The likelihood of the event will be the same for both Cost and Schedule, regardless of impact.
4. Impact is a measure of the event's effect on project objectives with relation to scope, cost, and/or schedule -- **Negligible**, **Marginal**, **Significant**, **Critical**, or **Crisis.** Impacts on Project Cost may vary in severity from impacts on Project Schedule.
5. Risk Level is the resultant of Likelihood and Impact **Low**, **Moderate**, or **High**. Refer to the matrix located at top of page.

6. Variance Distribution refers to the behavior of the individual risk item with respect to its potential effects on Project Cost and Schedule. For example, an item with clearly defined parameters and a solid most likely scenario would probably follow a
7. The responsibility or POC is the entity responsible as the Subject Matter Expert (SME) for action, monitoring, or information on the PDT for the identified risk or opportunity.
8. Correlation recognizes those risk events that may be related to one another. Care should be given to ensure the risks are handled correctly without a "double counting."
9. Affected Project Component identifies the specific item of the project to which the risk directly or strongly correlates.
10. Project Implications identifies whether or not the risk item affects project cost, project schedule, or both. The PDT is responsible for conducting studies for both Project Cost and for Project Schedule.
11. Results of the risk identification process are studied and further developed by the Cost Engineer, then analyzed through the Monte Carlo Analysis Method for Cost (Contingency) and Schedule (Escalation) Growth.

MS Coastal Barrier Islands Risk Summary

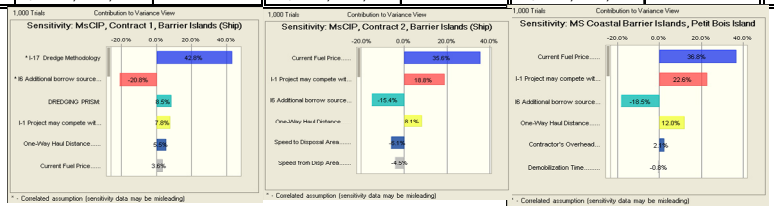
Background:

The project delivery team (PDT) conducted the initial risk development meeting on July 31,2008, identifying 23 separate risk items. Of these items, six are identified to be at a High Cost Risk level, nine at a Moderate Cost Risk level, and eight at a Low Cost Risk. In developing the Risk Analysis for the project, the High Cost Risk Items are the focus of attention.

The current scope of the project is to move 22 million yards of sand to restore the Barrier Islands off the coast of Mississippi. A gap in one of the islands will be repaired, additional sand will be placed around a Civil War era fort, and an offshore placement will be made to provide material to naturally wash ashore on the islands. The placement areas are all within a National Park Service (NPS) boundary. USACE and NPS are working together closely on this project and have agreed on the scope and conduct of the work proposed. The project scope and quantity of material to be moved and placed is fixed by agreement with NPS at 22 million yards. Once placed and accepted, the material will not be replenished under this program if damaged.

Risk Register Development:

The estimates prepared for the feasibility study are based on the assumptions that the program will be authorized and receive adequate funding to execute three contracts to complete the project over a 4-year period. The intent is to allow contractors flexibility in schedule to minimize impact to the other normally scheduled dredging activities in the Gulf Region. The borrow source is identified as being approximately 45nm away in the open ocean. Several other closer deposits may be suitable for borrow sources. However, the survey has not been completed to determine the suitability of the sand deposits. The PDT has a high degree of confidence that the other potential areas identified as borrow sources will be suitable for usage. It should be noted that the PDT has developed the project in an attempt to mitigate many of the factors identified within the risk analysis. The high cost risk items identified by the team are:



- Project Competing with other Programs
- Project Schedule
- Borrow source location
- Incomplete data and survey
- Dredge Methodology
- Fuel Pricing

In examining these High Cost Risk items (Project Competing with other Programs), Project Schedule risk has been mitigated through the development of the current proposed contract structure and period of performance. The potential for local inflation rates higher than the national average is still of concern with respect to the project schedule. The Borrow Source and survey are interdependent, as the survey will determine the suitability of other borrow sources and are combined to one element for analysis. Dredge Methodology is directly correlated to the borrow source, as the distance to the source will have significant impact on the equipment used. Methodology has the largest impact on the proposed contract for Camille. Fuel price fluctuations are identified within the risk cells embedded into the CEDEP estimate with a range of $4 to $7.

Results:

Overall, the risk profile of the project is approximately 33%. Each of the three contracts was modeled separately, and the totals were summed to determine the overall risk for the project. The sensitivity of each of the contracts showed that the dredge methodology, fuel price, borrow source, and competing projects are the largest contributors to risk.

This alternative consists of combining Option K from each of the three counties under LOD-2 which was "60-foot Wide by 2-foot Berm w/ Plants and Fencing" into a single contract. The sand for Jackson & Hancock berm construction will be obtained from inland, commercial sources and will be trucked to the project. Sand for Harrison berm will be by small dredge from near shore borrow. The fencing will wooden dune fencing and will be constructed on both sides of the berm for the entire length. The project will consist of placing the sand into the 60 foot wide by 2-foot high berm, adding the plants on top of the berm on 30-inch centers, then adding the fencing on each side of the planted berm. There will be a one-year warranty for 75% survival rate that is included in the Period of Performance shown below.

Price Level ly Aug 08

FEASIBILITY STUDY

Estimated by	CESAM-EN-E, Cost Engineering Branch
Designed by	CESAM-EN-E, Mobile District, Corps of Engineers
Prepared by	Joseph Ellsworth
Preparation Date	8/14/2008
Effective Date of Pricing	8/14/2008
Estimated Construction Time	Days

Joseph H. Ellsworth

BASIS of COST ESTIMATE and RATIONALE

Feasibility Estimate is based on Historical Data, Recent Pricing, and Estimator's Judgment. Estimate is structured and priced as a General Prime contractor supported by major subcontractors. Anticipated bidding conditions and construction duration with reasonable schedules are considered Normal. Unit cost as shown in estimate, are fair and reasonable rates based on fair market value. Estimates represent Current Contract Cost (price level Aug 08). The Non-structural and Real Estate Cost were prepared by the Savannah & Huntington Districts.

Price Level of Estimate is Aug 08.

Project Life is assumed as 50 years in Cost Estimate.

30 Feature Account, Planning, Engineering & Design was developed and assigned at 8% by the PDT. This is the percentage that has historically been used for these types of civil works projects. Eight percent was used in the Interim MsCIP projects which was reviewed and approved and included in the Chief's Report.

31 Feature Account, Construction Management was developed and assigned at 6% by the PDT. This is the percentage that has historically been used for these types of civil works projects. Six percent was used in the Interim MsCIP projects which was reviewed & approved and included in the Chief's Report.

Contingency was jointly developed and assigned by the Project Delivery Team. The Contingency percentage at 25% reflects the possibility of changes in quantity estimates and unknowns associated with the unit price. The contingency factor used does not vary throughout the cost estimate. It was determined and agreed upon by the Project Delivery Team that a high rate be used primarily due to risk, degree of confidence, and the project not being of the normal design.

Markups for subcontractors are included in the unit prices and include such items as field overheads, home office expenses, profit, bond and insurance.

Mobilization Preparatory Work & Demobilization are derived within the estimate generally at 2.5 % +- of construction cost excluding the Misc Items cost. Dredging cost is derived by CEDEP.

Miscellaneous Items represent cost where quantities were not available, such items as signage, construction site/staging restoration, silt fencing, site access, etc. These cost are derived within the estimate at .25 percent (.25%) of construction cost excluding Mob & Demob Cost

Unit Prices, for such items as site work, planting, fencing, etc., were based on Historical Data, Recent Pricing, Estimator's Judgment, and Cost derivation using MCACES / MII estimating systems.

8/5/2008 Joseph H. Ellsworth

Quantities listed within the estimates represent Major Elements of the Project Scope and were furnished by the Project Delivery Team. Where quantities were not available, assumptions were made based on historical information and Estimator's judgment.

Beach & Dune Planting (Sea Oats & Grass) and Fencing are based on recent cost provided by the Local sponsor, Harrison County Public Works, Ms. Quantities were derived

Date	Author	Note

from using historical photographs of the barrier islands and estimating that beach & dune area. The Corps worked with the National Park Service and also the State of Mississippi, Department of Marine Resources in order to come up with this required acre estimates. Sea oats are typically concentrated on the top of the dune and some on the slopes; thus, the team estimated that only approximately 140 plants would be planted per acre.

The following Contractor Markups are applied to the Cost to Prime Direct Cost:

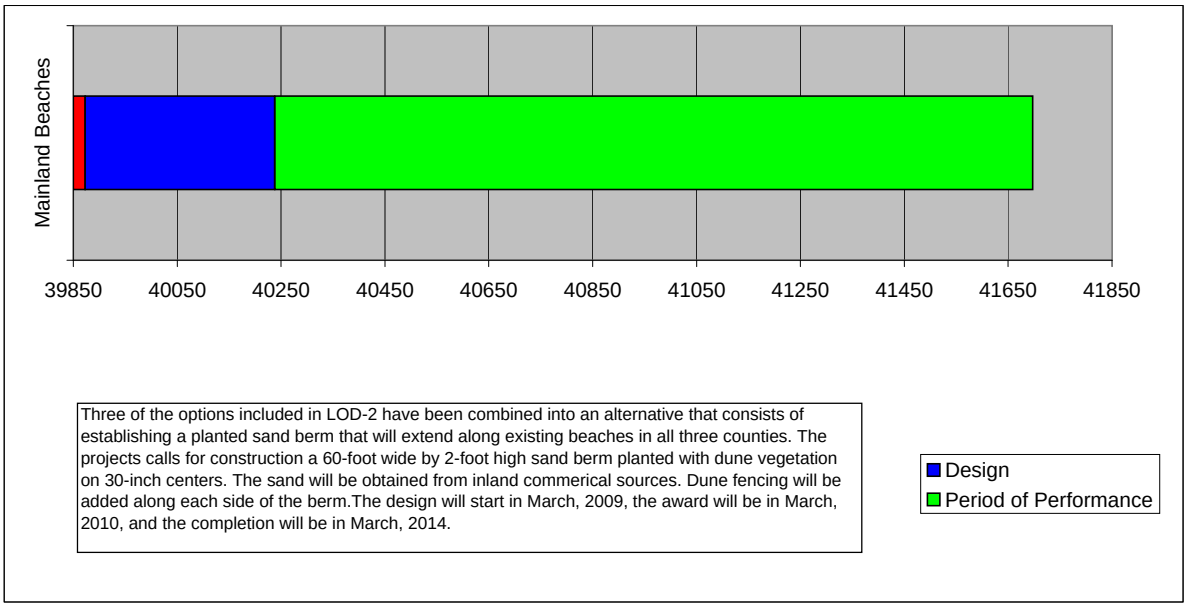
Contractor's Field Overhead @ 12%

Contractor's Home Office (G&A) @ 8%

Profit @ 10%

Bond @ 1.2%

Miss. Gross Receipts Tax @ 3.5%



Listed are all Cost Engineering Personnel that worked on the Feasibility Cost Estimate.
Joseph H. Ellsworth, Lead Cost Engineer
Gary Payton, Cost Engineer
George F. Rush, Civil Engineer, Dredging
Michael A. McKown, Geo Tech Engineer
Lloyd Oliver, Structural Engineer
Richard W. Harvey, Mechanical Engineer
John R. Thomas, Real Estate Specialist
Donald A. Whitmore, Civil Engineer- Non-Structural Estimates
Jennifer L. Jacobson, Environmentalist

Three of the options included in LOD-2 have been combined into an alternative that consists of establishing a planted sand berm that will extend along existing beaches in all three counties. The projects calls for construction a 60-foot wide by 2-foot high sand berm planted with dune vegetation on 30-inch centers. The sand will be obtained from inland commerical sources. Dune fencing will be added along each side of the berm.The design will start in March, 2009, the award will be in March, 2010, and the completion will be in March, 2014.

The project will also include selective clearing and snagging from the mouth of adjacent Turkey Creek upstream 4.5 miles. Selective clearing and snagging would remove obstructions such as debris dams and excessive sedimentation that hinders the flow through the Turkey Creek channel. The main purpose of the selective clearing and snagging is to make sure that induced damages do not occur due to the construction of the recommended levees. The selective clearing and snagging work will follow Stream Obstruction Removal Guidelines established by the American Fisheries Society.

The levee project consists of an earthen dike around the northern, western, and southern side of the neighborhood, and a concrete "t"-wall structure along the eastern side. The structure will constructed to elevation 21 ft NAVD88. A pumping station will be included to relieve the interior flooding. New culverts will be installed in the levee. The earthen part of the levee will have a 12-ft top width and 1 vertical to 3 horizontal sideslopes. Ditches next to the levee will convey water ponding against the levee to the outlets. Closure gates will be installed on the two existing access streets to the subdivision. An emergency access/egress street will be included on the north side of the neighborhood. An overflow section will be included to provide for controlled overtopping.

Forest Heights Work Description

Price Level Aug 08

FEASIBILITY STUDY

Estimated by	CESAM-EN-E, Cost Engineering Branch
Designed by	CESAM-EN-E, Mobile District, Corps of Engineers
Prepared by	Joseph H. Ellsworth
Preparation Date	8/7/2008
Effective Date of Pricing	8/7/2008
Estimated Construction Time	1,080 Days

Date	Author	Note
	Joseph H. Ellsworth	BASIS of COST ESTIMATE and RATIONALE Feasibility Estimate is based on Historical Data, Recent Pricing, and Estimator's Judgment. Estimate is structured and priced as a General Prime contractor supported by major subcontractors. Anticipated bidding conditions and construction duration with reasonable schedules are considered Normal. Unit cost as shown in estimate, are fair and reasonable rates based on fair market value. Estimates represent Current Contract Cost (price level Aug 08). Price Level of Estimate is Aug 08. Project Life is assumed as 50 years in Cost Estimate. 30 Feature Account, Planning, Engineering & Design was developed and assigned at 8% by the PDT. This is the percentage that has historically been used for these types of civil works projects. Eight percent was used in the Interim MsCIP projects which was reviewed and approved and included in the Chief's Report. 31 Feature Account, Construction Management was developed and assigned at 6% by the PDT. This is the percentage that has historically been used for these types of civil works projects. Six percent was used in the Interim MsCIP projects which was reviewed & approved and included in the Chief's Report. Contingency was jointly developed and assigned by the Project Delivery Team. The Contingency percentage at 25% reflects the possibility of changes in quantity estimates and unknowns associated with the unit price. The contingency factor used does not vary throughout the cost estimate. It was determined and agreed upon by the Project Delivery Team that a high rate be used primarily due to risk, degree of confidence, and the project not being of the normal design. Markups for subcontractors are included in the unit prices and include such items as field overheads, home office expenses, profit, bond and insurance. Mobilization Preparatory Work & Demobilization are derived within the estimate generally at 2.5 % +- of construction cost excluding the Misc Items cost. Miscellaneous Items represent cost where quantities were not available, such items as signage, construction site/staging restoration, silt fencing, site access, etc. These cost are derived within the estimate at .25 percent+- (.25%) of construction cost excluding Mob & Demob Cost Unit Prices, for such items as site work, earthwork, etc., were based on Historical Data, Recent Pricing, Estimator's Judgment, and Cost derivation using MCACES / MII estimating systems.
8/5/2008	Joseph H. Ellsworth	Quantities listed within the estimates represent Major Elements of the Project Scope and were furnished by the Project Delivery Team. Where quantities were not available, assumptions were made based on historical information and Estimator's judgment. The following Contractor Markups are applied to the Cost to Prime Direct Cost: Contractor's Field Overhead @ 12%

Date	Author	Note
		Contractor's Home Office (G&A) @ 8%
		Profit @ 10%
		Bond @ 1.2%
		Miss. Gross Receipts Tax @ 3.5%
		Listed are all Cost Engineering Personnel that worked on the Feasibility Cost Estimate. Joseph H. Ellsworth, Lead Cost Engineer Gary Payton, Cost Engineer George F. Rush, Civil Engineer, Dredging Michael A. McKown, Geo Tech Engineer Lloyd Oliver, Structural Engineer Richard W. Harvey, Mechanical Engineer John R. Thomas, Real Estate Specialist Donald A. Whitmore, Civil Engineer- Non-Structural Estimates Jennifer L. Jacobson, Environmentalist

The project consists of an elevation 21.0 NAVD88 earthen dike w/12-ft crest and 1 on 3 sideslopes.except for a concrete “t”-wall structure along the eastern side. Ditches and a pumping station will be included to relieve the interior flooding. Closure gates will be installed on the two existing access streets. An emergency access ramp will be included on the north side. An overflow section will be included to provide for controlled overtopping. Includes selective clearing and snagging from the mouth of adjacent Turkey Creek upstream 4.5 miles. The design will start in March of 2009, the award will be in September, 2009, and the completion will be March, 2011.

2. Maintain vegetation (Mandatory) by mowing 1st year and Burn 1st year; Burn every 3 years for life of project.

1. Filling in ditches (Mandatory to achieve overall restoration project).

The restoration site is primarily comprised of a degraded pine savannah wetland. Several miles of ditches have been excavated throughout the site. Additionally, an elevated railway berm fragments the wetland habitat substantially altering hydrology of the wetlands located to the north. The following measures were developed:
Turkey Creek Proposed Action

BASIS of COST ESTIMATE and RATIONALE

Feasibility Estimate is based on Historical Data, Recent Pricing, and Estimator's Judgment. Estimate is structured and priced as a General Prime contractor supported by major subcontractors. Anticipated bidding conditions and construction duration with reasonable schedules are considered Normal. Unit cost as shown in estimate, are fair and reasonable rates based on fair market value. Estimates represent Current Contract Cost (price level Aug 08). The Non-structural and Real Estate Cost were prepared by the Savannah & Huntington Districts.

Price Level of Estimate is Aug 08.

Project Life is assumed as 50 years in Cost Estimate.

01 Feature Account, Real Estate Cost was prepared by the Savannah District COE.

30 Feature Account, Planning, Engineering & Design was developed and assigned at 8% by the PDT. This is the percentage that has historically been used for these types of civil works projects. Eight percent was used in the Interim MsCIP projects which was reviewed and approved and included in the Chief's Report.

31 Feature Account, Construction Management was developed and assigned at 6% by the PDT. This is the percentage that has historically been used for these types of civil works projects. Six percent was used in the Interim MsCIP projects which was reviewed & approved and included in the Chief's Report.

Contingency was jointly developed and assigned by the Project Delivery Team. The Contingency percentage at 25% reflects the possibility of changes in quantity estimates and unknowns associated with the unit price. The contingency factor used does not vary throughout the cost estimate. It was determined and agreed upon by the Project Delivery Team that a high rate be used primarily due to risk, degree of confidence, and the project not being of the normal design.

Markups for subcontractors are included in the unit prices and include such items as field overheads, home office expenses, profit, bond and insurance.

Mobilization Preparatory Work & Demobilization are derived within the estimate generally at 2.5 % +- of construction cost excluding the Misc Items cost.

Miscellaneous Items represent cost where quantities were not available, such items as signage, construction site/staging restoration, silt fencing, site access, etc. These cost are derived within the estimate at .25 percent (.25%) of construction cost excluding Mob & Demob Cost

Unit Prices, for such items as site work, earthwork, stone protection, concrete, reinforcing, etc., were based on Historical Data, Recent Pricing, Estimator's Judgment, and Cost derivation using MCACES / MII estimating systems.

8/5/2008 Joseph H. Ellsworth

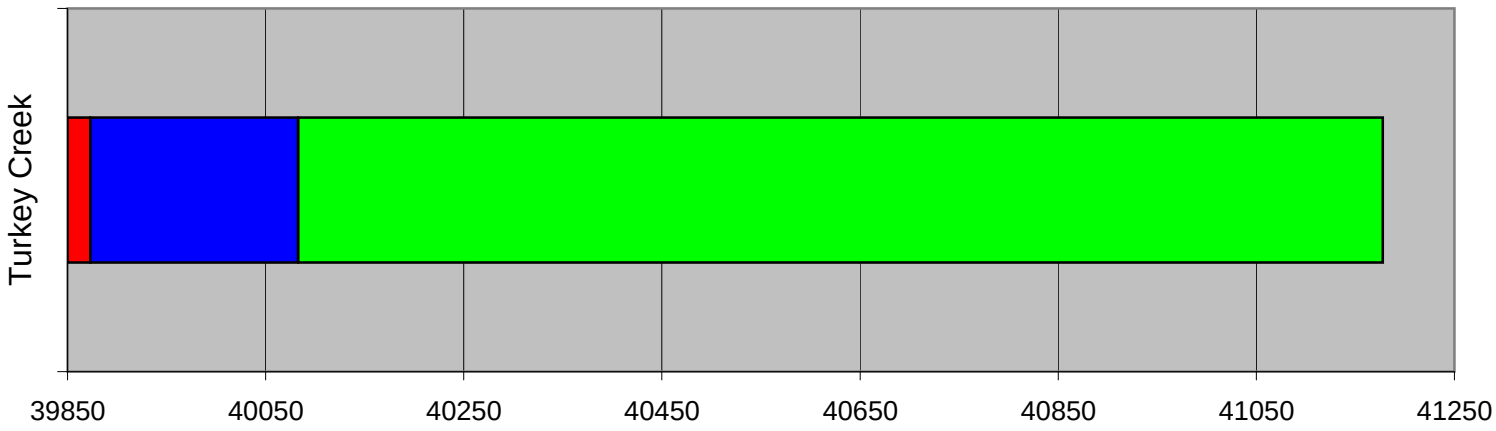
The following Contractor Markups are applied to the Cost to Prime Direct Cost:

Contractor's Field Overhead @ 12%

Date	Author	Note

Contractor's Home Office (G&A) @ 8%

Profit @ 10%



Bond @ 1.2%

Miss. Gross Receipts Tax @ 3.5%

Listed are all Cost Engineering Personnel that worked on the Feasibility Cost Estimate.

The restoration is comprised of restoration of a degraded pine savannah wetland. Several miles of ditches at the site will be filled. Additionally, an elevated railway berm that fragments the wetland habitat will be removed along with roadbeds and any other fill. Invasive vegetation will be controlled by mowing and burning. The design will start in March of 2009, the award will be in October, 2009, and the completion will be October, 2012.

3. Filling in 100% of existing artificial ditches. (Mandatory)

2. 100% removal of exotics and plantation pine; maintain removal of exotic plant species in all areas over project lifetime. (Mandatory in all plans).

1. Maintain native savanna vegetation. (Mandatory) by mowing 1st year and Burn 1st year; Burn every 3 years for life of project.

The restoration site contains 385 acres to be restored to wet pine savanna. This area was planted in plantation pine during the 1960s and ditches and stormwater lines were constructed in the early 1970s in anticipation of residential development of the site. The long-term exclusion of fire and the invasion of non-native species such as Cogongrass and Chinese Tallowtree have severely degraded the site. The following measures were developed:

BASIS of COST ESTIMATE and RATIONALE

Feasibility Estimate is based on Historical Data, Recent Pricing, and Estimator's Judgment. Estimate is structured and priced as a General Prime contractor supported by major subcontractors. Anticipated bidding conditions and construction duration with reasonable schedules are considered Normal. Unit cost as shown in estimate, are fair and reasonable rates based on fair market value. Estimates represent Current Contract Cost (price level Aug 08). The Non-structural and Real Estate Cost were prepared by the Savannah & Huntington Districts.

Price Level of Estimate is Aug 08.

Project Life is assumed as 50 years in Cost Estimate.

01 Feature Account, Real Estate Cost was prepared by the Savannah District COE.

06 Feature Account, Preservation - Mitigation-Tidal quantites were based on impacts of new footprint plus mitigated factor which was determined and coordinated by other agencies. Unit cost were derived and based on historical data.

30 Feature Account, Planning, Engineering & Design was developed and assigned at 8% by the PDT. This is the percentage that has historically been used for these types of civil works projects. Eight percent was used in the Interim MsCIP projects which was reviewed and approved and included in the Chief's Report.

31 Feature Account, Construction Management was developed and assigned at 6% by the PDT. This is the percentage that has historically been used for these types of civil works projects. Six percent was used in the Interim MsCIP projects which was reviewed & approved and included in the Chief's Report.

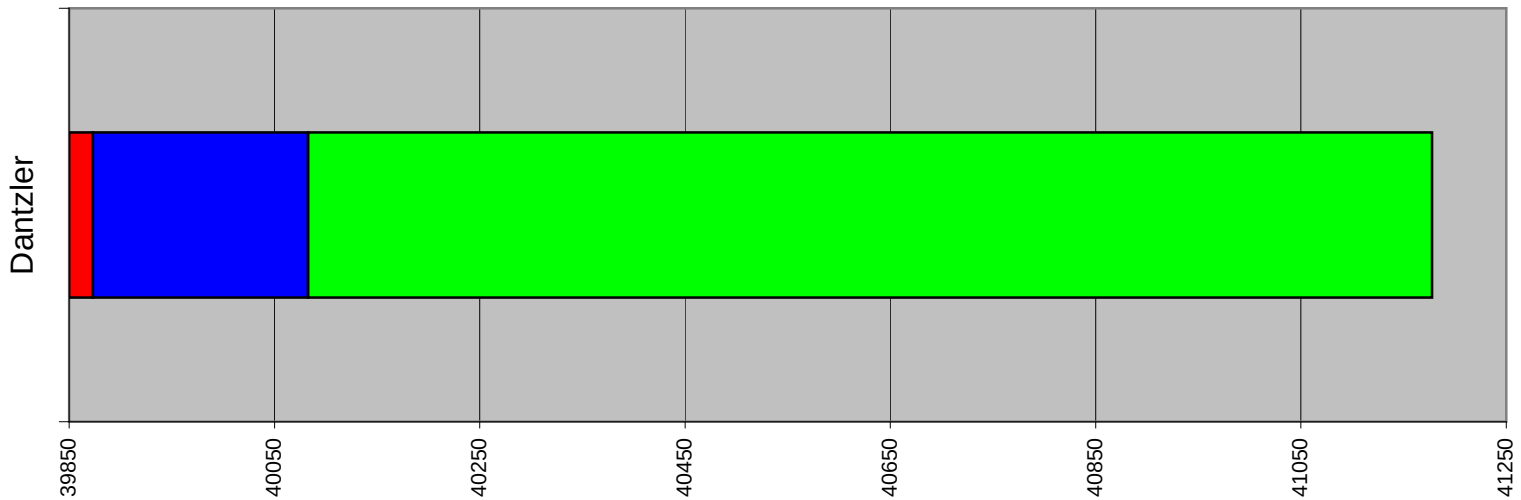
Contingency was jointly developed and assigned by the Project Delivery Team. The Contingency percentage at 25% reflects the possibility of changes in quantity estimates and unknowns associated with the unit price. The contingency factor used does not vary throughout the cost estimate. It was determined and agreed upon by the Project Delivery Team that a high rate be used primarily due to risk, degree of confidence, and the project not being of the normal design.

Markups for subcontractors are included in the unit prices and include such items as field overheads, home office expenses, profit, bond and insurance.

Mobilization Preparatory Work & Demobilization are derived within the estimate generally at 2.5 % +- of construction cost excluding the Misc Items cost.

Miscellaneous Items represent cost where quantities were not available, such items as signage, construction site/staging restoration, silt fencing, site access, etc. These cost are derived within the estimate at .25 percent (.25%) of construction cost excluding Mob & Demob Cost

Unit Prices, for such items as site work, earthwork, stone protection, concrete, reinforcing, etc., were based on Historical Data, Recent Pricing, Estimator's Judgment, and Cost derivation using MCACES / MII estimating systems.



8/5/2008 Joseph H. Ellsworth

The following Contractor Markups are applied to the Cost to Prime Direct Cost:

The restoration site contains 385 acres to be restored to wet pine savanna. The long-term exclusion of fire and the invasion of non-native species such as Cogongrass and Chinese Tallowtree have severely degraded the site and will be removed along with other exotic plant species. Existing ditches will be filled. The site will be mowed and burned as part of the vegetation maintenance. The design will start in March of 2009, the award will be in October, 2009, and the completion will be October, 2012.

4.□ative Vegetation Planting at 1 meter spacing

3.Ÿilling in 100% of existing artificial ditches/channels.

2.‘00% removal of exotics from non-excavated areas and maintain removal of exotic plant species in all areas over project lifetime. (Mandatory in all plans).

1.žxcavation of old fill material (includes 90-95% removal of existing exotic species in excavated areas) (Mandatory).

The restoration site contains 62 acres of emergent tidal marsh to be restored. The remaining 61 acres of scrub shrub wetland habitat would remain. The tidal marshes in this area were ditched during the 1960s causing changes in the natural hydrology and subsequent changes in the species composition. Hurricane Katrina left extensive debris fields and sedimentation in the area and destroyed many native trees and vegetation. Due to the loss of native species this area has a severe infestation of the invasive Chinese Tallow tree, which is invading the marshes and the adjacent flatwoods. For increased habitat diversity, higher elevations containing shrub/scrub wetland plant species would remain in order to enhance diversity within the restoration site. The following measures were developed:
Admiral Island Proposed Action

BASIS of COST ESTIMATE and RATIONALE

Feasibility Estimate is based on Historical Data, Recent Pricing, and Estimator's Judgment. Estimate is structured and priced as a General Prime contractor supported by major subcontractors. Anticipated bidding conditions and construction duration with reasonable schedules are considered Normal. Unit cost as shown in estimate, are fair and reasonable rates based on fair market value. Estimates represent Current Contract Cost (price level Aug 08).

Price Level of Estimate is Aug 08.

Project Life is assumed as 50 years in Cost Estimate.

06 Feature Account, Preservation - Mitigation-Tidal quantites were based on impacts of new footprint plus mitigated factor which was determined and coordinated by other agencies. Unit cost were derived and based on historical data.

30 Feature Account, Planning, Engineering & Design was developed and assigned at 8% by the PDT. This is the percentage that has historically been used for these types of civil works projects. Eight percent was used in the Interim MsCIP projects which was reviewed and approved and included in the Chief's Report.

31 Feature Account, Construction Management was developed and assigned at 6% by the PDT. This is the percentage that has historically been used for these types of civil works projects. Six percent was used in the Interim MsCIP projects which was reviewed & approved and included in the Chief's Report.

Contingency was jointly developed and assigned by the Project Delivery Team. The Contingency percentage at 25% reflects the possibility of changes in quantity estimates and unknowns associated with the unit price. The contingency factor used does not vary throughout the cost estimate. It was determined and agreed upon by the Project Delivery Team that a high rate be used primarily due to risk, degree of confidence, and the project not being of the normal design.

Markups for subcontractors are included in the unit prices and include such items as field overheads, home office expenses, profit, bond and insurance.

Mobilization Preparatory Work & Demobilization are derived within the estimate generally at 2.5 % +- of construction cost excluding the Misc Items cost.

Miscellaneous Items represent cost where quantities were not available, such items as signage, construction site/staging restoration, silt fencing, site access, etc. These cost are derived within the estimate at .25 percent+- (.25%) of construction cost excluding Mob & Demob Cost

Unit Prices, for such items as site work, earthwork, etc., were based on Historical Data, Recent Pricing, Estimator's Judgment, and Cost derivation using MCACES / MII estimating systems.

8/5/2008 Joseph H. Ellsworth

Quantities listed within the estimates represent Major Elements of the Project Scope and were furnished by the Project Delivery Team. Where quantities were not available, assumptions were made based on historical information and Estimator's judgment.

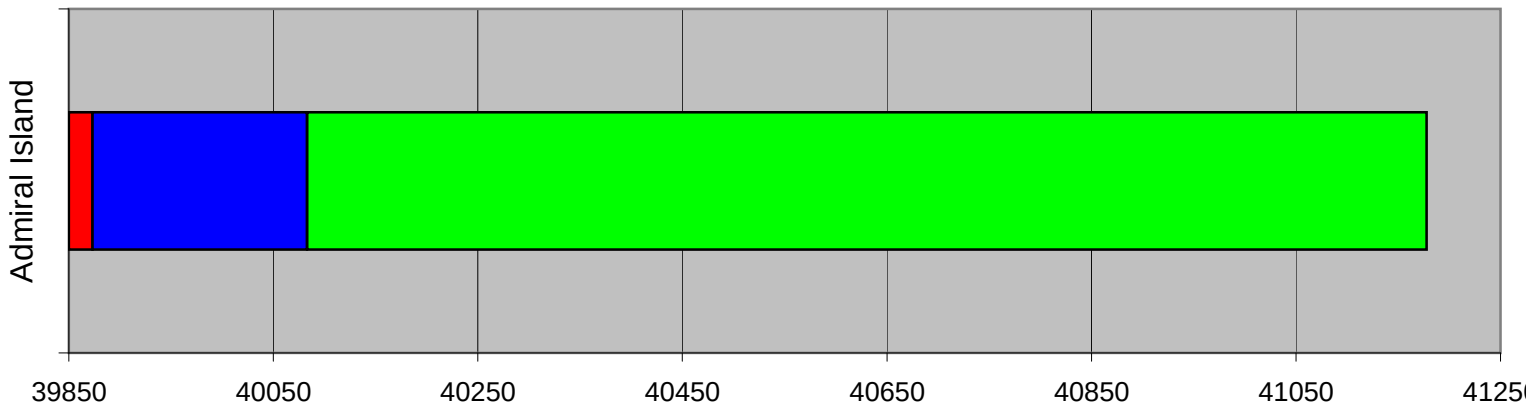
The following Contractor Markups are applied to the Cost to Prime Direct Cost:

Date	Author	Note

Contractor's Field Overhead @ 12%

Contractor's Home Office (G&A) @ 8%

Profit @ 10%



Bond @ 1.2%

Miss. Gross Receipts Tax @ 3.5%

The restoration site contains 62 acres of emergent tidal marsh to be restored by removing fill and planting native vegetation on 1-meter spacing and filling existing ditches. The remaining 61 acres of scrub shrub wetland habitat would remain. Due to the loss of native species this area has a severe infestation of the invasive Chinese Tallow tree, which is invading the marshes and the adjacent flatwoods. For increased habitat diversity, higher elevations containing shrub/scrub wetland plant species would remain in order to enhance diversity within the restoration site with 100% removal of exotics from non-excavated areas. The design will start in March of 2009, the award will be in October, 2009, and the completion will be October, 2012.

4. Native Vegetation Planting at 1 meter spacing

3. Filling in 100% of existing artificial ditches/channels

2. 100% removal of exotics from non-excavated areas and maintain removal of exotic species (Chinese Tallow, Phragmites, Cogon Grass) in all areas over project lifetime. (Mandatory in all plans).

1. Excavation of old fill material (includes 90-95% removal of existing exotic species in excavated areas) (Mandatory)

The restoration project consists of 110 acres to be restored to tidal marsh and while the remaining 38 acres would remain scrub/shrub wetland habitat. The area presently consists of previously filled marsh areas that were developed into a residential community. The majority of residences were severely damaged or completely destroyed during the hurricanes of 2005. The following measures were developed:

Bayou Cumbest

Price Level ly Aug 08

Date	Author	Note
	Joseph H. Ellsworth	BASIS of COST ESTIMATE and RATIONALE Feasibility Estimate is based on Historical Data, Recent Pricing, and Estimator's Judgment. Estimate is structured and priced as a General Prime contractor supported by major subcontractors. Anticipated bidding conditions and construction duration with reasonable schedules are considered Normal. Unit cost as shown in estimate, are fair and reasonable rates based on fair market value. Estimates represent Current Contract Cost (price level Aug 08). Price Level of Estimate is Aug 08. Project Life is assumed as 50 years in Cost Estimate. 30 Feature Account, Planning, Engineering & Design was developed and assigned at 8% by the PDT. This is the percentage that has historically been used for these types of civil works projects. Eight percent was used in the Interim MsCIP projects which was reviewed and approved and included in the Chief's Report. 31 Feature Account, Construction Management was developed and assigned at 6% by the PDT. This is the percentage that has historically been used for these types of civil works projects. Six percent was used in the Interim MsCIP projects which was reviewed & approved and included in the Chief's Report. Contingency was jointly developed and assigned by the Project Delivery Team. The Contingency percentage at 25% reflects the possibility of changes in quantity estimates and unknowns associated with the unit price. The contingency factor used does not vary throughout the cost estimate. It was determined and agreed upon by the Project Delivery Team that a high rate be used primarily due to risk, degree of confidence, and the project not being of the normal design. Markups for subcontractors are included in the unit prices and include such items as field overheads, home office expenses, profit, bond and insurance. Mobilization Preparatory Work & Demobilization are derived within the estimate generally at 2.5 % +- of construction cost excluding the Misc Items cost. Miscellaneous Items represent cost where quantities were not available, such items as signage, construction site/staging restoration, silt fencing, site access, etc. These cost are derived within the estimate at .25 percent +-(.25%) of construction cost excluding Mob & Demob Cost Unit Prices, for such items as site work, earthwork, planting, etc., were based on Historical Data, Recent Pricing, Estimator's Judgment, and Cost derivation using MCACES / MII estimating systems.
8/5/2008	Joseph H. Ellsworth	The following Contractor Markups are applied to the Cost to Prime Direct Cost: Contractor's Field Overhead @ 12% Contractor's Home Office (G&A) @ 8% Profit @ 10% Bond @ 1.2% Miss. Gross Receipts Tax @ 3.5% Listed are all Cost Engineering Personnel that worked on the Feasibility Cost Estimate.

4. Add culverts (Mandatory)

3. Excavate and remove existing roadbeds and any additional fill (Mandatory)

2. Maintain vegetation (Mandatory) by mowing 1st year and Burn 1st year; Burn every 3 years for life of project.

1. Filling in ditches (Mandatory)

The restoration site is an interim buy-out project currently being implemented. The site consists of 149 acres bisected by an elevated railroad atop an earthen berm. The site received severe flood damages during the hurricanes of 2005 and previous storm events. Historically, the site consisted of pine savannah wetlands. It is assumed that removal of utilities, building slabs, and roadways would be completed as part of the ongoing interim project. The following restoration measures were developed:

Franklin Creek

Price Level Aug 08

FEASIBILITY STUDY

BASIS of COST ESTIMATE and RATIONALE

Feasibility Estimate is based on Historical Data, Recent Pricing, and Estimator's Judgment. Estimate is structured and priced as a General Prime contractor supported by major subcontractors. Anticipated bidding conditions and construction duration with reasonable schedules are considered Normal. Unit cost as shown in estimate, are fair and reasonable rates based on fair market value. Estimates represent Current Contract Cost (price level Aug 08). The Non-structural and Real Estate Cost were prepared by the Savannah & Huntington Districts.

Price Level of Estimate is Aug 08.

Project Life is assumed as 50 years in Cost Estimate.

30 Feature Account, Planning, Engineering & Design was developed and assigned at 8% by the PDT. This is the percentage that has historically been used for these types of civil works projects. Eight percent was used in the Interim MsCIP projects which was reviewed and approved and included in the Chief's Report.

31 Feature Account, Construction Management was developed and assigned at 6% by the PDT. This is the percentage that has historically been used for these types of civil works projects. Six percent was used in the Interim MsCIP projects which was reviewed & approved and included in the Chief's Report.

Contingency was jointly developed and assigned by the Project Delivery Team. The Contingency percentage at 25% reflects the possibility of changes in quantity estimates and unknowns associated with the unit price. The contingency factor used does not vary throughout the cost estimate. It was determined and agreed upon by the Project Delivery Team that a high rate be used primarily due to risk, degree of confidence, and the project not being of the normal design.

Markups for subcontractors are included in the unit prices and include such items as field overheads, home office expenses, profit, bond and insurance.

Mobilization Preparatory Work & Demobilization are derived within the estimate generally at 2.5 % +- of construction cost excluding the Misc Items cost.

Miscellaneous Items represent cost where quantities were not available, such items as signage, construction site/staging restoration, silt fencing, site access, etc. These cost are derived within the estimate at .25 percent (.25%) of construction cost excluding Mob & Demob Cost

Unit Prices, for such items as site work, earthwork, stone protection, concrete, reinforcing, etc., were based on Historical Data, Recent Pricing, Estimator's Judgment, and Cost derivation using MCACES / MII estimating systems.

8/5/2008 Joseph H. Ellsworth

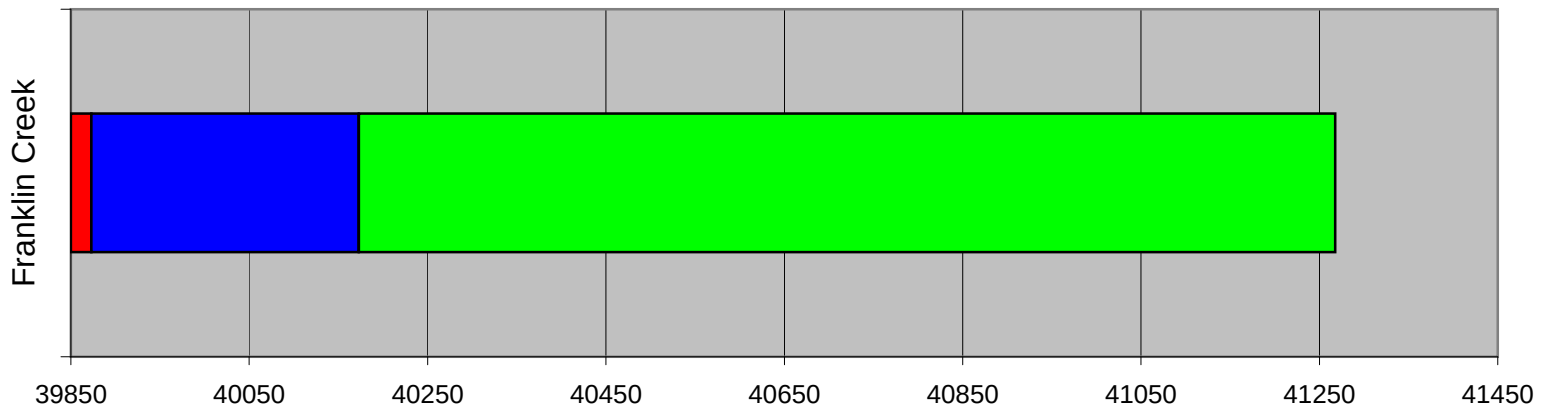
The following Contractor Markups are applied to the Cost to Prime Direct Cost:

Contractor's Field Overhead @ 12%

Contractor's Home Office (G&A) @ 8%

Date	Author	Note

Profit @ 10%



Bond @ 1.2%

Miss. Gross Receipts Tax @ 3.5%

Create additional marsh habitat area adjacent to the existing created marsh area.

Lengthen stone containment dikes on northern and southern ends as a result of Section 204; and

Analyze new stone training dikes on the northern and southern ends of the islands as a result of Section 204;

Add/Replace material in the Section 204 containment dike;

Repair/Replace the Section 204 containment dike;

Deer Island restoration consists of a combination of the following alternatives to form the recommended plan:

Deer Island also includes the following aspects in the MsCIP effort.

The proposed project for Deer Island will provide for ecosystem restoration as well as preservation of critical coastal wetlands by restoring portions of the island and its shoreline lost during storm events. The island also provides storm protection from surge, wave action and wind for the adjacent coastal portion of the City of Biloxi, Mississippi. The proposed project will consist of three components: shoreline restoration in the Grand Bayou area of Deer Island with beach, dune, marsh and maritime forest reestablishment; restoration of the west end breach area with reestablishment of maritime forest area; and, restoration of the remaining shoreline areas along the seaward shoreline with beach, dune, marsh and maritime forest reestablishment. Fill material will be obtained from an offshore borrow area located approximately 500 feet off the southern shoreline of Deer Island. The offshore borrow area adjacent to the island would be approximately 1,000 feet wide, 6 feet deep, with a distance equal to the length of the project area. The borrow site is far enough from and is of sufficiently shallow depth to not affect shoreline stability. The wind and wave attack at Deer Island is generally southwest to northeast which is expected to push material along the shoreline. Material from the borrow area will be cast on the existing shoreline for beach nourishment via a hydraulic dredge. After filling, environmental plantings will be made to establish the maritime forest and aquatic marsh in the restored area.

The proposed project will provide for ecosystem restoration and preservation of critical coastal wetlands. The island also provides storm protection from surge, wave action and wind for the adjacent coastal portion of the City of Biloxi, Mississippi. The proposed project will consist of three components: shoreline restoration in the Grand Bayou area of Deer Island with beach, dune, marsh and maritime forest reestablishment; restoration of the west end breach area with reestablishment of maritime forest area; and, restoration of the remaining shoreline areas along the seaward shoreline with beach, dune, marsh and maritime forest reestablishment. Fill material will be obtained from an offshore borrow area located approximately 500 feet off the southern shoreline of Deer Island. Material from the borrow area will be cast on the existing shoreline for beach nourishment via a hydraulic dredge. After filling, environmental plantings will be made to establish the maritime forest and aquatic marsh in the restored area. The design will start in March of 2009, the award will be in September, 2009, and the completion will be March, 2011.

The MsCIP environmental effort will: (1) restore SAV beds in Bayou Cumbest adjacent to the Grand Bay NERR that have been lost since the 2005 hurricanes through transplanting involving participation by the local community groups and students of the local universities and (2) determine the effectiveness of three transplanting methods (i.e. (1) a donor site, (2) harvesting plant sprigs with one or more meristems (growth regions), or (3) spreading seeds or mature flowering shoots over the restoration site) for restoring R. maritima in bayous, streams, and brackish marshes by quarterly monitoring using volunteers. After transplanting, quarterly monitoring for two years will be conducted to determine plant establishment, photosynthesis, growth, and expansion.
The first goal of the proposed community-based restoration project in the Grand Bay NERR will result in restoration of up to 5 acres of R. maritima resulting in the recovery of an equal amount of SAV habitat to that lost during the 2005 hurricane season (Figure 5.5.1-1). Secondly, the Corps, Mobile District proposed to evaluate 3 restoration techniques to demonstrate their feasibility for larger restoration projects. Finally, the volunteer involvement and educational outreach will increase awareness of the importance of SAV habitat in Mississippi Sound and provide coastal managers and restoration practitioners with the knowledge of techniques to maximize their return on dollars spent.
SAVs Write Up

BASIS of COST ESTIMATE and RATIONALE

Feasibility Estimate is based on Historical Data, Recent Pricing, and Estimator's Judgment. Estimate is structured and priced as a General Prime contractor supported by major subcontractors. Anticipated bidding conditions and construction duration with reasonable schedules are considered Normal. Unit cost as shown in estimate, are fair and reasonable rates based on fair market value. Estimates represent Current Contract Cost (price level Aug 08). The Non-structural and Real Estate Cost were prepared by the Savannah & Huntington Districts.

Price Level of Estimate is Aug 08.

Project Life is assumed as 50 years in Cost Estimate.

30 Feature Account, Planning, Engineering & Design was developed and assigned at 8% by the PDT. This is the percentage that has historically been used for these types of civil works projects. Eight percent was used in the Interim MsCIP projects which was reviewed and approved and included in the Chief's Report.

31 Feature Account, Construction Management was developed and assigned at 6% by the PDT. This is the percentage that has historically been used for these types of civil works projects. Six percent was used in the Interim MsCIP projects which was reviewed & approved and included in the Chief's Report.

Contingency was jointly developed and assigned by the Project Delivery Team. The Contingency percentage at 25% reflects the possibility of changes in quantity estimates and unknowns associated with the unit price. The contingency factor used does not vary throughout the cost estimate. It was determined and agreed upon by the Project Delivery Team that a high rate be used primarily due to risk, degree of confidence, and the project not being of the normal design.

Markups for subcontractors are included in the unit prices and include such items as field overheads, home office expenses, profit, bond and insurance.

Miscellaneous Items represent cost where quantities were not available, such items as signage, construction site/staging restoration, silt fencing, site access, etc. These cost are derived within the estimate at .25 percent (.25%) of construction cost excluding Mob & Demob Cost

Unit Prices, for such items as site work, earthwork, stone protection, concrete, reinforcing, etc., were based on Historical Data, Recent Pricing, Estimator's Judgment, and Cost derivation using MCACES / MII estimating systems.

8/5/2008 Joseph H. Ellsworth

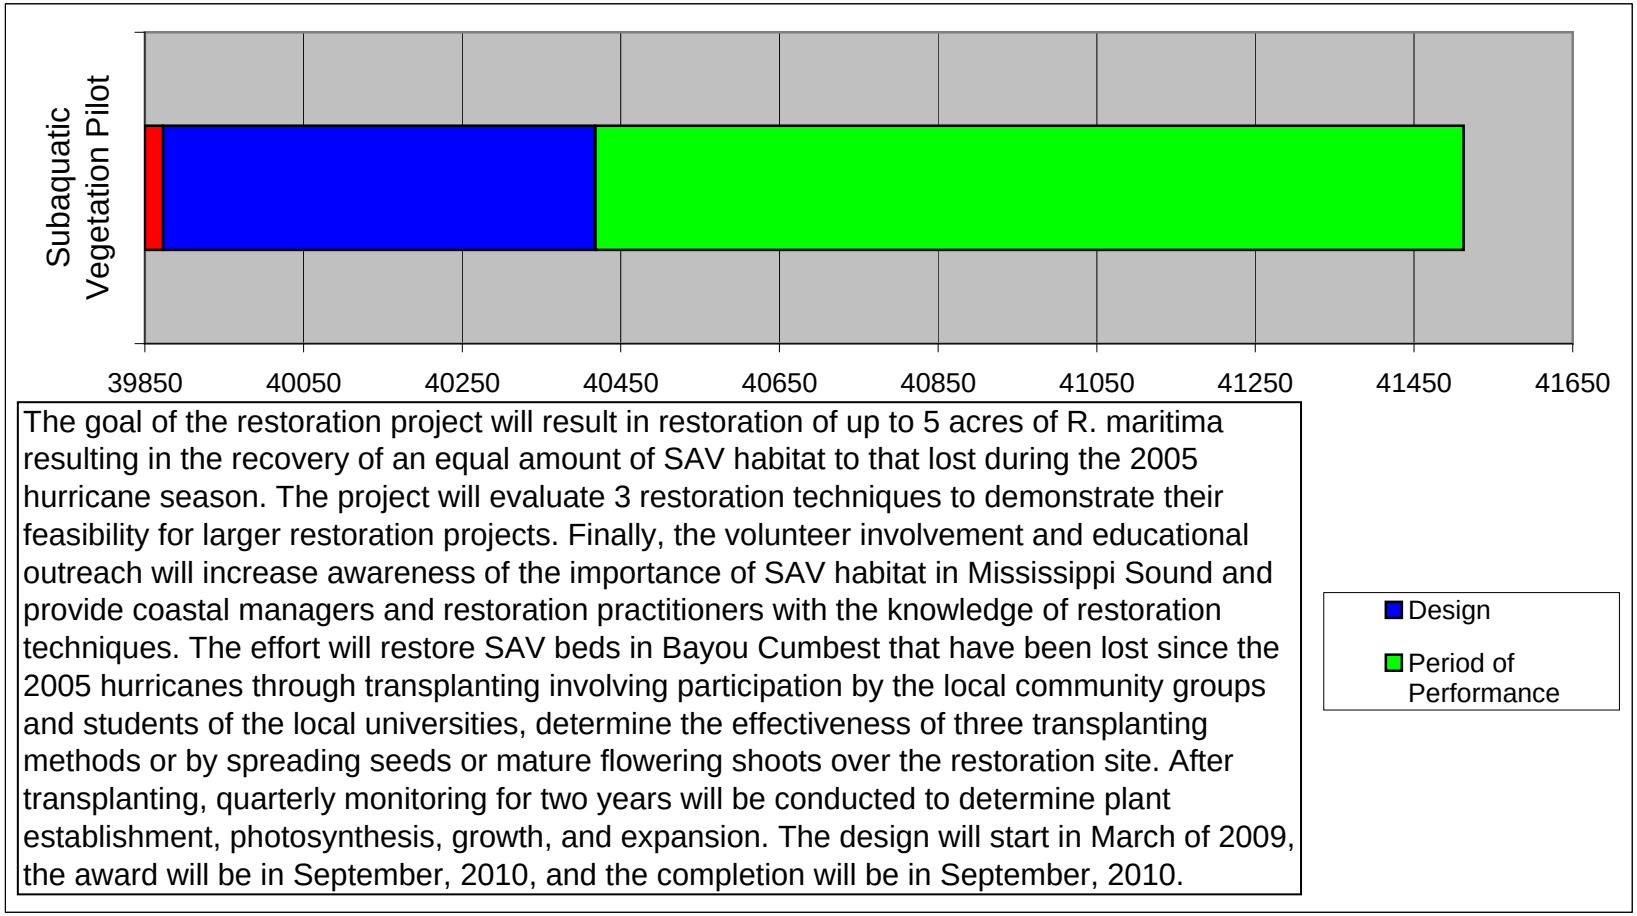
The following Contractor Markups are applied to the Cost to Prime Direct Cost:

Contractor's Field Overhead @ 12%

Contractor's Home Office (G&A) @ 8%

Profit @ 10%

Date	Author	Note



Bond @ 1.2%

Miss. Gross Receipts Tax @ 3.5%

Date	Author	Note
9/22/2007	Don Whitmore	SCOPE

This cost estimate is comprised of 8 model estimates. Each of these estimates pertains to the floodproofing of residential structures on the Gulf Coast.

1. New house construction on pier foundation at a finished first floor of 6 FT above low ground.

2. New house construction on pier foundation at a finished first floor of 15 FT above low ground.

3. Raising of existing house on slab foundation to a finished first floor of 6 Ft above low ground.

4. Raising of existing house on slab foundation to a finished first floor of 15 Ft above low ground.

5. New mobile home construction on pier foundation at a finished first floor of 6 FT above low ground.

6. New mobile home construction on pier foundation at a finished first floor of 15 FT above low ground.

7. Raising of existing mobile home to a finished first floor of 6 Ft above low ground.

8. Raising of existing mobile home to a finished first floor of 15 Ft above low ground.

ASSUMPTION AND EXCLUSIONS

1. All existing structures are assumed to be either a permanent structure with a slab foundation or a mobile home.

2. For the permanent structure alternatives (models 1 - 4), each structure is assumed to have a living area of 1,600 SF. This assumption applies to either the structure replacement alternative or the structure raise alternative. For the purposes of this estimate, the cost engineer has assumed a simple rectangular house with outside dimensions of 25' x 64'. This yields an area of 1,600 SF and a perimeter of 178 LF.

3. The replacement of permanent structures is based on wooden pier construction to the appropriate elevation (in this case, either 6' or 15' above low ground) and the construction of a new house on this foundation. The foundation quantities and costs for this alternative were detailed by the cost engineer based on the above assumptions. The cost of the new structure above the sill plate was estimated using the Marshall & Swift Residential Estimator 7 software, assuming the construction of an average quality home in the Gulfport, MS area.

4. The raising of an existing permanent construction home has been based on a segmental conrete pile foundation. The prime example of this technology is the "Davie Shoring" system (see www.davieshoring.com). It involves tunneling by hand under the slab foundation, cutting existing pile (if applicable), and installing the conrete piles one segment at a time by hydraulic jack until the piles reach refusal. The house is then raised on these piles and a new foundation is constructed. Depending on the structure's final height above low ground, the final foundation would be either the concrete segmental piles with a decorative facade or it would be CIP reinforced concrete with continuous grade beams. For these alternatives, the cost engineer simply obtained a quote from Davie for cost of providing a turnkey structure elevation.

5. For the mobile home construction (models 5 - 8), the replacement of eligible structures would be to construct a wooden pier foundation and place a modular home on this foundation. The structure is assumed to have a living area of 1,000 SF. For the purposes of this estimate, the cost engineer has assumed a simple rectangular mobile home with outside dimension of 14' x 72', which is very conservative by most standards for mobile homes. This yields an area of 1,008 SF and a perimeter of 172 LF. The foundation and living area cost has been estimated in a manner similar to that of the permanent structures (assumption #3), which is also considered by the cost engineer to be very conservative for modular home construction.

6. The raising of an existing mobel home assumes the same method of raising as the permanent construction approach (assumption #4, above). The primary difference is the structure area has been reduced from 1,600 SF to 1,000 SF.

Date Author **Note**

7. In each of the higher elevation alternatives (i.e., those involving a structure whose first floor elevation is 15' above low ground), a 300 SF storage area has been included as part of the foundation.

8. In all cases, allowances have been made for the following:
- asbestos abatement ($1000 per structure)
- aerator systems to be installed on 10% of the structures
- temporary housing
- utility connections (except for the raise alternatives whose quoted price already included utility hookup)

9. Site work costs for items such as landscaping, sidewalks and driveways as well as exterminating, landscaping and construction cleanup have been based on LRH's 202 floodproofing cost model. Parameters were used as input into the model that would fit each of the above descriptions (models 1 - 8), and the total values for these items have been included in this estimate as lump sums.

10. Davis-Bacon labor rates were not used in this estimate. According to the PDT, the project will be formulated such that the requirement to use Davis-Bacon will not apply. At this time, the precise labor rate requirement is unknown. Consequently, the cost engineer left the labor rates undisturbed for each of the various cost sources. As an example, the MEANS cost manuals are based on national average labor rates. However, no attempt was made to adjust the items priced by the MEANS cost manual to account for a different labor rate.

FEATURE ACCOUNTS

01 Lands & Damages: Since these estimates only apply to the floodproofing of structures on site and not the acquisition and demolition of structures, the only costs shown in this account are for administration purposes. An allowance of $5,000 per structure has been made based on LRH's Section 202 floodproofing program. This price would include contingencies.

11 Levees, Floodwalls, & Floodproofing: Costs have been developed in accordance with the above assumptions.

30 Preconstruction Engineering & Design: An allowance of $13,000 per structure has been made based on LRH's Section 202 floodproofing program. This price would include contingencies.

31 Supervision & Administration: An allowance of $7,000 per structure has been made based on LRH's Section 202 floodproofing program. This price would include contingencies.

LEVEL OF EFFORT

This estimate is considered to be preliminary in nature and is to be used as such. The scopes provided to the cost engineer were very general. Indeed, the level of effort put forth by the cost engineer is commensurate to the general nature of the design.

PRICE LEVEL

The costs contained within this estimate have been prepared at a Price Level equivalent to 1 October 2007. Contingency has been included at 25% for model estimates 1 - 4. For the mobile home alternatives, however, a contingency of only 20% was applied due to the very conservative nature of the approach in estimating.

COST SOURCES

A variety of cost sources were used in preparing this estimate. The primary sources were:

- Marshall & Swift Residential Estimator 7
- LRH's Section 202 Implementation Floodproofing Cost Model

			53.19		*70.28*	*25.00*	*87.85*
New Structure - Above Sill Plate	1,600.00	SF	85,104.00	27,346.85	112,450.85	28,112.71	140,563.57
(Note: Cost estimated by Marshall-Swift for an average quality 1600 SF structure in the Gulfport, MS area. See backup sheet from Marshall Swift. Estimated unit price is $68.35/SF including O&P. Since the pier foundation is estimated elsewhere in this estimate, the standard CIP wall foundation should be deleted from this Marshall-Swift estimate. Also, the overhead and profit should be deleted here. MII will add O&P to the direct cost unit price under the Project Item tab. O&P is estimated to be 14.5% in the Marshall-Swift program. The foundation is estimated to cost $67/LF of perimeter (MEANS), including O&P. $67/LF x (25x2 + 64x2) = $11,926. Now, $11,926 / 1600 SF = $7.45/SF that is to be deducted from the estimated unit price for new construction. So, $68.35/SF - $7.45/SF = $60.90/SF (w/ O&P) Subtracting O&P, $60.90/SF / 1.145 = $53.19/SF<---)

Since the pier foundation is estimated elsewhere in this estimate, the standard CIP wall foundation should be deleted from this Marshall-Swift estimate. Also, the overhead and profit should be deleted here. MII will add O&P to the direct cost unit price under the Project Item tab. O&P is estimated to be 14.5% in the Marshall-Swift program. The foundation is estimated to cost $67/LF of perimeter (MEANS), including O&P. $67/LF x (25x2 + 64x2) = $11,926. Now, $11,926 / 1600 SF = $7.45/SF that is to be deducted from the estimated unit price for new construction. So, $68.35/SF - $7.45/SF = $60.90/SF (w/ O&P) Subtracting O&P, $60.90/SF / 1.145 = $53.19/SF<---)

Description	Quantity	UOM	CostToPrime	PrimeCMU	ContractCost	Contingency	ProjectCost
11 - Levees, Floodwalls, and Floodproofing	**1.00**	**EA**	**96,434.27**	**30,363.07**	**126,797.34**	**25,359.47**	**152,156.81**
			53.19		*70.28*		*84.34*
Structure Above Sill Plate	**1,000.00**	**SF**	**53,190.00**	**17,091.78**	**70,281.78**	**14,056.36**	**84,338.14**
			53.19		*70.28*	*20.00*	*84.34*
New Structure - Above Sill Plate	1,000.00	SF	53,190.00	17,091.78	70,281.78	14,056.36	84,338.14
(Note: Cost estimated by Marshall-Swift for an average quality 1000 SF structure in the Gulfport, MS area. See backup sheet from Marshall Swift. Estimated unit price is $68.35/SF including O&P. Since the pier foundation is estimated elsewhere in this estimate, the standard CIP wall foundation should be deleted from this Marshall-Swift estimate. Also, the overhead and profit should be deleted here. MII will add O&P to the direct cost unit price under the Project Item tab. O&P is estimated to be 14.5% in the Marshall-Swift program. The foundation is estimated to cost $67/LF of perimeter (MEANS), including O&P. $67/LF x (25x2 + 64x2) = $11,926. Now, $11,926 / 1600 SF = $7.45/SF that is to be deducted from the estimated unit price for new construction. So, $68.35/SF - $7.45/SF = $60.90/SF (w/ O&P) Subtracting O&P, $60.90/SF / 1.145 = $53.19/SF<---)

			53.19		*70.28*	*20.00*	*84.34*
New Structure - Above Sill Plate	1,000.00	SF	53,190.00	17,091.78	70,281.78	14,056.36	84,338.14
(Note: Cost estimated by Marshall-Swift for an average quality 1000 SF structure in the Gulfport, MS area. See backup sheet from Marshall Swift. Estimated unit price is $68.35/SF including O&P. Since the pier foundation is estimated elsewhere in this estimate, the standard CIP wall foundation should be deleted from this Marshall-Swift estimate. Also, the overhead and profit should be deleted here. MII will add O&P to the direct cost unit price under the Project Item tab. O&P is estimated to be 14.5% in the Marshall-Swift program. The foundation is estimated to cost $67/LF of perimeter (MEANS), including O&P. $67/LF x (25x2 + 64x2) = $11,926. Now, $11,926 / 1600 SF = $7.45/SF that is to be deducted from the estimated unit price for new construction. So, $68.35/SF - $7.45/SF = $60.90/SF (w/ O&P) Subtracting O&P, $60.90/SF / 1.145 = $53.19/SF<---)

Note: This cost estimate was originally developed using the RS MEANS Square Foot Costs Cost 2007 Manual, 28th Annual Edition. Subsequent to this initial effort, the estimate has been updated to FY 2009 costs (PL 1 October 2008) using OMB inflation factors. The factors used were 1.072 (7.2%) for labor costs and 1.050 (5.0%) for non-labor costs. The cost model used can be found on pages 220 and 221. USACE-CELRH-EC-CE provided parametric inputs such as building construction type, building size, and a basic description of site work and land requirements. The MEANS model has been replicated in this worksheet so as to readily make the proper adjustments.

Structure Function: City Hall & Public Works Facility

Input Parameters:

Price Level (PL) =	1-Oct-2008
Area of New Building (SF) =	7,400
Length of Building (LF) =	110.00
Number of Stories (EA) =	1
Story Height (FT) =	12.00
Total Area of New Site (ACR) =	1.00
Existing Facility to Be Demolished (SF) =	5,000
Interior Partition Height (FT) =	10.00
Roof / Footprint Ratio (SF/SF) =	1.10

Calculated Parameters:

Width of Building (LF) =	67.00
Perimeter of New Building (LF) =	354
Area-Perimeter Ratio (SF/LF) =	20.90
Width-Length Ratio (LF/LF) =	0.61
Exterior Wall Area (SF) =	4,248
Unit Price, Project Cost ($/SF) =	227.95
Roof Area (SF) =	8,140

Building Element	Construction Task		Quantity	Unit	Unit Cost	Total Direct Cost (PL 1 Oct 2007)	Cost Per S.F.	Feature Account

TOTAL	**1,349,492**	**337,373**	**1,686,865**

Therefore, the total estimated cost at PL 1-Oct-2008 to relocate a 7,400 SF city hall & public works facility is $1,687,000 which equates to $228 per SF. This estimate is based on assumed dimensions of 110 LF by 67 LF yielding a perimeter of 354 LF. Also, the structure was assumed to be 1 story tall with an assumed story height of 12.00 FT. The demo of a 5,000 SF existing structure has been included. The purchase and development of 1.00 acre of land is included.

Note: This cost estimate was originally developed using the RS MEANS Square Foot Costs Cost 2007 Manual, 28th Annual Edition. Subsequent to this initial effort, the estimate has been updated to FY 2009 costs (PL 1 October 2008) using OMB inflation factors. The factors used were 1.072 (7.2%) for labor costs and 1.050 (5.0%) for non-labor costs. The cost model used can be found on pages 184 and 185. USACE-CELRH-EC-CE provided parametric inputs such as building construction type, building size, and a basic description of site work and land requirements. The MEANS model has been replicated in this worksheet so as to readily make the proper adjustments.

Structure Function: Police Station & Courthouse

Input Parameters:

Price Level (PL) =	1-Oct-2008
Area of New Building (SF) =	10,400
Length of Building (LF) =	120.00
Number of Stories (EA) =	2
Story Height (FT) =	12.00
Total Area of New Site (ACR) =	0.75
Existing Facility to Be Demolished (SF) =	0
Interior Partition Height (FT) =	10.00
Roof / Footprint Ratio (SF/SF) =	1.10

Calculated Parameters:

Width of Building (LF) =	87.00
Perimeter of New Building (LF) =	414
Area-Perimeter Ratio (SF/LF) =	25.12
Width-Length Ratio (LF/LF) =	0.73
Exterior Wall Area (SF) =	9,936
Unit Price, Project Cost ($/SF) =	361.54
Roof Area (SF) =	5,720

TOTAL	**3,008,046**	**752,011**	**3,760,057**

Therefore, the total estimated cost at PL 1-Oct-2008 to relocate a 10,400 SF police station & courthouse is $3,760,000 which equates to $362 per SF. This estimate is based on assumed dimensions of 120 LF by 87 LF yielding a perimeter of 414 LF. Also, the structure was assumed to be 2 stories tall with an assumed story height of 12.00 FT. The demo of no existing structure has been included. The purchase and development of 0.75 acres of land is included.

Note: This cost estimate was originally developed using the RS MEANS Square Foot Costs Cost 2007 Manual, 28th Annual Edition. Subsequent to this initial effort, the estimate has been updated to FY 2009 costs (PL 1 October 2008) using OMB inflation factors. The factors used were 1.072 (7.2%) for labor costs and 1.050 (5.0%) for non-labor costs. The cost model used can be found on pages 126 and 127. USACE-CELRH-EC-CE provided parametric inputs such as building construction type, building size, and a basic description of site work and land requirements. The MEANS model has been replicated in this worksheet so as to readily make the proper adjustments.

Structure Function: Fire Station

Input Parameters:

Price Level (PL) =	1-Oct-2008
Area of New Building (SF) =	5,900
Length of Building (LF) =	98.00
Number of Stories (EA) =	1
Story Height (FT) =	14.00
Total Area of New Site (ACR) =	0.50
Existing Facility to Be Demolished (SF) =	4,720
Interior Partition Height (FT) =	10.00
Roof / Footprint Ratio (SF/SF) =	1.10

Calculated Parameters:

Width of Building (LF) =	60.00
Perimeter of New Building (LF) =	316
Area-Perimeter Ratio (SF/LF) =	18.67
Width-Length Ratio (LF/LF) =	0.61
Exterior Wall Area (SF) =	4,424
Unit Price, Project Cost ($/SF) =	253.38
Roof Area (SF) =	6,490

TOTAL	**1,195,955**	**298,989**	**1,494,944**

Therefore, the total estimated cost at PL 1-Oct-2008 to relocate a 5,900 SF fire station is $1,495,000 which equates to $253 per SF. This estimate is based on assumed dimensions of 98 LF by 60 LF yielding a perimeter of 316 LF. Also, the structure was assumed to be 1 story tall with an assumed story height of 14.00 FT. The demo of a 4,720 SF existing structure has been included. The purchase and development of 0.50 acres of land is included.

Note: This cost estimate was originally developed using the RS MEANS Square Foot Costs Cost 2007 Manual, 28th Annual Edition. Subsequent to this initial effort, the estimate has been updated to FY 2009 costs (PL 1 October 2008) using OMB inflation factors. The factors used were 1.072 (7.2%) for labor costs and 1.050 (5.0%) for non-labor costs. The cost model used can be found on pages 144 and 145. USACE-CELRH-EC-CE provided parametric inputs such as building construction type, building size, and a basic description of site work and land requirements. The MEANS model has been replicated in this worksheet so as to readily make the proper adjustments.

FOREWORD

This document is one of a number of technical appendices to the *Mississippi Coastal Improvements Program (MsCIP) Comprehensive Plan and Integrated Feasibility Report and Environmental Impact Statement*.

The *Mississippi Coastal Improvements Program (MsCIP) Comprehensive Plan Integrated Feasibility Report and Environmental Impact Statement* provides systems-based solutions and recommendations that address: hurricane and storm damage reduction, ecosystem restoration and fish and wildlife preservation, reduction of damaging saltwater intrusion, and reduction of coastal erosion. The recommendations contained in the Main Report/EIS also provide measures that aid in: greater coastal environmental and societal resiliency, regional economic re-development, and measures to reduce long-term risk to the public and property, as a consequence of hurricanes and coastal storms. The recommendations cover a comprehensive package of projects and activities, which treat the environment, wildlife, and people, as an integrated system that requires a multi-tiered and phased approach to recovery and risk reduction, irrespective of implementation authority or agency.

The MsCIP Study Area

The purpose of the Comprehensive Plan Report is to present, to the Congress of the United States, the second of two packages of recommendations (i.e., the first being the "interim" recommendations funded in May 2007, and the second, this "final" response, as directed by the Congress), directed at recovery of vital water and related land resources damaged by the hurricanes of 2005, and development of recommendations for long-term risk reduction and community and environmental

resiliency, within the three-county, approximately 70 mile-long coastal zone, including Mississippi Sound and its barrier islands, of the State of Mississippi.

This appendix, the Main Report/EIS, and all other appendices and supporting documentation, were subject to Independent Technical Review (ITR) and an External Peer Review (EPR). Both review processes will have been conducted in accordance with the Corps "Peer Review of Decision Documents" process, has been reviewed by Corps staff outside the originating office, conducted by a Regional and national team of experts in the field, and coordinated by the National Center of Expertise in Hurricane and Storm Damage Protection, North Atlantic Division, U.S. Army Corps of Engineers.

The report presents background on the counties that comprise the Mississippi coastline most severely impacted by the Hurricanes of 2005, their pre-hurricane conditions, a summary of the effects of the 2005 hurricane season, problem areas identified by stakeholders and residents of the study area, a summary of the approach used in analyzing problems and developing recommendations directed at assisting the people of the State of Mississippi in recovery, recommended actions and projects that would assist in the recovery of the physical and human environments, and identification of further studies and immediate actions most needed in a comprehensive plan of improvements for developing a truly resilient future for coastal Mississippi.

This Risk Appendix contains a discussion of the risk-based planning approach used by the MsCIP study team, for the analysis and characterization to the public and stakeholders of risks associated with existing and future without-project conditions, the potential risks, uncertainties and consequences associated with potential problem-solving measures (also known as "with-project" conditions), the incorporation of, and use of a stakeholder-involved risk-aware "weighting" process, referred to as a "Risk-Informed Decision Framework", or RIDF, that elicited stakeholder preferences on specific metrics used in the analysis, evaluation, and comparison of alternatives; and finally, the incorporation and consideration of all information received as stakeholder input, and a full consideration of all factors, in the screening of the final array of alternatives, and ultimately, the selection of recommendations contained in the Main Report/EIS.

The use of the Risk-Informed Decision Framework (RIDF) in the Mississippi Coastal Improvements Project, comprehensive plan development, was done better inform and involve stakeholders in the planning process, with the ultimate goal of creating solutions to reduce the potential for continued residual risk from flood and storm surge inundation, coastal wetlands loss and degradation, erosion, and saltwater intrusion, in ways that would promote greater resiliency in the future. The RIDF provided procedures that have aided decision makers in identifying planning objectives, performance metrics, and stakeholder priorities, in a transparent format. The RIDF utilizes techniques from the fields of risk and decision analysis to simply and clearly show decision makers and the public the risks, costs and consequences of flood control, coastal restoration, and hurricane protection by accommodating multiple objectives, conflicting stakeholder values, both qualitative and quantitative assessments of performance, and uncertainty in the natural, social, and economic environment.

Each appendix functions as a complete technical document, but is meant to support one particular aspect of the feasibility study process. However, because of the complexity of the plan formulation process used in this planning study, the information contained herein should not be used without parallel consideration and integration of all other appendices, and the Main Report/EIS that summarizes all findings and recommendations.

EXECUTIVE SUMMARY

This Risk Appendix outlines the approach taken in the Mississippi Coastal Improvements Program (MsCIP) Comprehensive Plan study effort, to evaluating, communicating, and incorporating consideration of risks, uncertainties, and consequences, in the comparison, screening, and selection of alternative plans.

The MsCIP approach utilized a multi-step process, which incorporated:

1) Evaluation and assessment of potential risks, uncertainties and consequences associated with existing conditions, future "without-project" conditions, and numerous "with-project" plans;

2) Application of the Corps' "Risk and Uncertainty" analysis procedures, which assess and incorporate probabilities and uncertainties in the technical evaluation process;

3) Education of the public, agencies and other interests, in the inherent risks, uncertainties and potential consequences or any course of action, (including doing nothing), in various public forums and workshops;

4) Incorporation of the newly-implemented "Risk-Informed Decision Framework" (RIDF) methodology, that considered the factors (or "metrics") of greatest importance to the stakeholders and technical evaluators, solicitation of public and agency input on potential plans, and their prioritization (i.e., "Stakeholder Preferences") and potential selection of Locally-Preferred Plans, and finally;

5) Comparison of alternative plans, including all risk factors, in a "System of Accounts" format, screening, and selection of Federally-recommended plans, as part of the full consideration of all economic, environmental, technical, societal, risk factors, and explicit requirements (including Congressional) directed at the study effort.

Risk Analysis using this set of procedures was a new approach for a Corps of Engineers study, as it required a more thorough assessment of all the risk factors involved, but also integration of more public and agency involvement in the discussion of, and prioritization of risk factors, in a better articulated explanation of how risk may determine alternative recommendation in the plan selection process, in some cases with clear direction resulting from the risks and consequences possible under various plans.

PART 5 – COMPARISON, SCREENING AND CONSIDERATION OF RISK IN THE PLAN SELECTION PROCESS 16

PART 1 – EVALUATION AND ASSESSMENT OF RISKS, UNCERTAINTIES, AND CONSEQUENCES

Evaluation and assessment of risk, uncertainties and consequences was the first step in the MsCIP risk assessment process.

The MsCIP team used standard conventions and definitions used in risk assessment, although some leeway was incorporated into the overall use of risk terminology, due to the on-going use of certain terms, such as "risk", in ways that are much broader than those in the risk assessment arena might use them. The broadest use of the term "Risk", as used in the MsCIP study, could be characterized as the potential for negative outcomes, under certain action and no-action conditions, both now and in the future. The public uses this term to refer to their own personal risks, be it risks to their health, income, residences, cultural integrity, or community, and thus, the MsCIP team had to adopt this convention. The MsCIP team also had to similarly use this term to characterize risks of environmental outcomes, such as functional damage to ecosystems, loss of species (or multiple species) integrity and survival, and many other negative outcomes. Because the public and stakeholders had to understand the nature of their risks and potential consequences for a large range of possible future conditions that by their nature were, in many cases, only qualitatively defined, the use of "risk" in this broader framework was by necessity, adopted.

"Risk ", in a narrower definition also used in the MsCIP study, could be defined as the probability of a certain outcome, under certain conditions. An example of this would be the probability (5% in any given year, for example) of a certain damage level, expressed in dollars ($10,000,000, for example), occurring in the event of a certain-sized hurricane-caused surge and wave depth and extent event. This could be expressed both as a probability of a certain outcome given a certain event, but can also be expressed as a sum of damages expected under a range of events, such as an average of all damages expected, over a time horizon such as fifty years, were nothing to be done to prevent those damages.

Risk, or the probability of certain events or outcomes, was more readily defined for some type of outcomes, such as hurricane-caused surge and wave depth, than for other types of outcomes, such as human reactions, or the number of deaths caused, by an oncoming hurricane. For some factors, probabilities were defined quantitatively; in many other cases, they could only be estimated qualitatively, as a range of possible outcomes.

The first phase of the data collection and characterization step involved the collection of all data associated with human and environmental outcomes to past hurricanes in this area of the Gulf Coast. Data collected included damages caused by various events, environmental conditions created by hurricanes and other large storm events, salinity and freshwater effects, erosion effects, and the human impacts of events, including deaths caused, human health and mental health effects, and human and environmental responses over time, economic (local, regional and national outcomes), response over time to relative sea level rise and developmental pressures, income and minority community responses, and many other probabilistic outcomes.

Most difficult to determine, were the hypothetical outcomes, both positive and negative, expected under future "without-project" conditions. This involved the development of outcomes in consideration of the numerous technical and environmental studies being developed in the course of the MsCIP study. In some cases, "risk" data were developed in express direction to expected negative outcomes resulting from certain course of action, particularly those concerned with human impacts as a result of certain plans being implemented.

The MsCIP study team used data furnished by a broad range of sources, to define risks associated with a large number of existing and future conditions, including the “No-Action”, and future with-project conditions for a large number of alternative plans. Many potential outcomes were developed in detailed discussions as to the nature of conditions under many future scenarios, and what the effects might be on the large array of resources. This data was used to populate a database, summarized in the System of Accounts tables given in the Main Report, where both quantitative and qualitative determinations of positive and negative outcomes are displayed, and the risks, uncertainties, and potential consequences of each, are compared.

“Uncertainty” as used in Corps studies, refers to the degree of uncertainty expressed by technical evaluators (or even in some cases by the public), that a certain outcome will occur under and certain condition. This could be expressed as a range of outcomes given a certain condition, an example being that experts predict that water depth may be as much as 20 feet and as little as 12 feet deep, under circumstances of a certain-magnitude hurricane event, at a certain location. In many cases, however, uncertainties regarding a certain outcome, could only be expressed in the broadest of terms. An example of this would the uncertainties regarding threats to human life under conditions such as the implementation of ring levees or surge barriers. It is, of course, highly uncertain as to how human beings will react to the approach of a hurricane event, given the uncertainties as to landfall, intensity, and other factors. This is complicated by the intervention of certain conditions like a surge barrier, behind which people may feel “protected”, or alternatively, very mush at risk. These determinations of risk and uncertainty played a large, although heavily dependent on qualitative assessment, role in decision-making on the part of the Federal response.

Assessment and characterization of risk and uncertainties led, as expected, to their incorporation in the technical analyses conducted under the MsCIP study effort, the second step of this process.

PART 2 – TECHNICAL RISK AND UNCERTAINTY

The second step of the risk assessment process was the incorporation of what the Corps refers to as "Risk and Uncertainty Analysis". This aspect of the risk analysis focuses on the evaluation of technical aspects of potential plans, that includes both estimation of probabilities of certain outcomes, but also the determination of uncertainties in any estimated outcome. Technical risk and uncertainty also included a measure of risk and uncertainty inherent in cost estimation.

Risk and uncertainty analysis is a comprehensive, statistically-based approach directed at identifying and incorporating uncertainties associated with key factors that are inherent in the determination of plans addressing flooding, hurricane surge, waves, and other destructive events, as well as those comprising key elements of ecosystem restoration planning, economic analysis, and cost estimating.

Key factors evaluated in the Risk and Uncertainty analysis conducted under the MsCIP study include: evaluating uncertainties in estimating surge (water surface) elevations and wave contributions to surge height, the extent of surge inundation by frequency of event (by use of multiple event modeling), the first floor elevation of structures, the magnitude of damages to both structures and contents, and risks in the estimation of costs associated with future events, including those of project or program implementation. In addition, uncertainty was an inherent factor in the environmental processes used to identify possible restoration sites. This uncertainty was primarily related to the scale of the existing data used to populate the GIS based Spatial Decision Support System (SDSS). In addition there is uncertainty in the benefit evaluation system used, the Hydrogeomorphic Methodology (HGM), due to the lack of time to completely ground truth the sites in question.

Risk and Uncertainty is a rigorous part of Corps of Engineer analyses and the planning process. Engineer Regulation 1105-2-101 defines risk as, "The probability an area will be flooded, resulting in undesirable consequences," and uncertainty as, "A measure of imprecision of knowledge of parameters and functions used to describe the hydraulic, hydrologic, geotechnical, and economic aspects of a project plan."

For the Mississippi Coastal Improvements Program (MsCIP) Comprehensive Plan, both risk and uncertainty played a vital role throughout the planning and selection process as well as the work conducted by each of the various technical aspects. While this section will paint a broad picture of the application of techniques used to address risk and uncertainty, the engineering, environmental, real estate, and economic appendices go into greater detail on how each discipline addressed these issues.

Estimation of risks and uncertainties associated with the MsCIP Comprehensive Plan study area, as defined by Congress, included estimation of physical outcomes across the three coastal counties of Mississippi; Hancock, Harrison and Jackson Counties from west to east respectively. Hancock, Harrison, and Jackson Counties include over 1,361 square miles, roughly 100 square miles larger than the state of Rhode Island and populations of 40,421, 171,875, and 130,577 respectively. The Maximum Probable Intensity (MPI) footprint, or the estimate of the maximum surge footprint, includes over 138,000 residential and commercial structures. Within these areas, surge from Hurricane Katrina significantly destroyed (50% or more structural damage) 32,446 structures, with another 15,000 to 25,000 sustaining moderate to minor damage. The sheer magnitude and scale of this area, along with the extent of the damage sustained, set the stage for much larger degrees of risk and uncertainty than exist in typical Corps Feasibility Studies.

Forecasting future scenarios is an important part of the Corps planning process. In order to evaluate the true risk and impacts over the period of analysis, all forecasts were created based on historic

and existing information, as well as quantitative and qualitative assessments of what is most likely to happen within the study area in the future. One method used was to identify the 'most likely' future, or the best guess about what may happen based on observed variables and assumptions of both natural and human behaviors. Another method used was to conduct scenario planning, where multiple future scenarios are created in order to evaluate what would happen if observed variables or assumptions do not happen as projected. Scenario planning attempts to answer the 'what if' questions that arise when making forecasting assumptions and predictions. For the MsCIP Comprehensive Study, the former method was chosen due to the size, scope, and complexity of the overall analysis, but with scenario testing used for the multiple possible futures possible under sea level rise and re-development possibilities.

The use of scenario planning allowed the MsCIP PDT the ability to evaluate the impacts of large uncertainties such as varying redevelopment types and the effects of relative sea level rise. Four future without-project scenarios were developed based on two redevelopment scenarios and two potential relative sea level rise scenarios. Redevelopment was assumed as either the rebuilding of the study area exactly as it was pre-Hurricane Katrina (residential redevelopment) or rebuilding similar to pre-Hurricane Katrina levels except for the vast waterfront coastline, which would rebuild as either condominiums or casinos (commercial redevelopment). Sea level rise and land surface subsidence have been taken into account as part of this study and is reported as "relative sea level rise" which accounts for both as a single value.

After the identification of the four potential future without-project scenarios, the next step was the evaluation of those scenarios using hydrodynamic and economic models. Hydraulic and hydrologic modeling efforts by a team of USACE, FEMA, NOAA, private sector and academic researchers have been working toward the definition of a new system for estimating hurricane inundation probabilities. Their work includes the use of multiple models such as the Planetary Boundary Layer Model (TC-96) which evaluates wind pressure fields, the Wave Attenuation Model (WAM) which evaluates offshore waves, the STWAVE near shore wave model, and the Advanced Circulation (ADCIRC) model which incorporates output from the other models into the storm surge modeling effort. Modeling inputs included a storm suite of over 150 storms covering ranges in variable drivers such as central pressure, radius to maximum winds, and forward speed. Outputs of the models were statistically analyzed using a modified Joint Probability Method with Optimal Sampling (JPM-OS). The underlying concept of the JPM-OS methodology is to provide a good estimate of the surge in as small a number of dimensions as possible, while retaining the effects of additional dimensions by including an $\boldsymbol{\varepsilon}$ term within the estimated Cumulative Distribution Function (CDF) for surges. The $\boldsymbol{\varepsilon}$ term is considered to include, at a minimum, tides, random variations in the Holland B parameter, track variations not captured in storm set, model errors (including errors in bathymetry, errors in model physics, etc.), and errors in wind fields due to neglect of variations not included in the Planetary Boundary Layer model winds. More detail on the JPM-OS method can be found in the Engineering Appendix (Appendix E)

The output of the JPM-OS modeling effort was provided to the Mobile District Engineering Division for the estimation of exceedence probability functions that were incorporated into the Hydrologic Engineering Center – Flood Damage Analysis (HEC-FDA) program. The HEC-FDA program uses risk-based analysis methods for evaluating flood damage and flood damage reduction alternatives. The program relies on hydrologic, hydraulic, and economic data input. Uncertainties in these data are input and used by the model for computing expected annual damages. HEC-FDA input variables that include uncertainty are the exceedance probability functions, depth damage relationships, first floor elevations, and structure and content values. The program's risk-based analysis methods conform to Corps of Engineers policy regulations. Outputs of the HEC-FDA program for each of the future without-project scenarios are detailed in the Economic Appendix

(Appendix B), and are included in the Risk Informed Decision Framework (RIDF) process outlined in later sections of this appendix.

Although there is some uncertainty associated with the environmental restoration evaluation process it is felt that these uncertainties are within the ranges of values used within the various models. The environmental team ground truthed a portion of each of the recommended sites to ensure that the proposed restoration activities would be achievable and that the restored sites would function as designed. The project is also recommending implementation of an adaptive management process and monitoring for all the proposed environmental restoration project elements. The techniques being proposed for restoration, e.g. excavation of fill, filling man-made ditches, mowing and burning etc., are tried and true proven restoration methods. Further only sites that contain wetland soils and are in the near vicinity of water courses are proposed for restoration. This will increase the probability of success for those sites proposed for restoration as tidal fringe wetlands.

Risk and Uncertainty outcomes were also incorporated into the risk database, summarized in the System of Accounts tables given in the Main Report. All of this data was used in the later phases of risk assessment and screening of alternatives ultimately leading to the selection of recommended actions.

PART 3 – EDUCATION OF STAKEHOLDERS

The third step of the risk assessment process was the characterization of risk, in terms that everyone could understand, and the dissemination of this information to the stakeholders. This was an extremely important part of the process, since the stakeholders were so interested in the planning process and its potential outcomes, but was doubly important given their participation in the next phase of study, the integration of Risk-Informed Decision Framework (RIDF), in which they would very actively participate, and for which good information on risks, uncertainties, and consequences was so important.

Data on the potential risks and consequences of the no-action plan, and the large number of potential alternatives plans addressing numerous identified problem areas and sites, was assembled and discussed by members of the study team, agency participants, and technical experts in each field. It was recognized that much of the data would be confusing to the public, and in fact, could actually cause the public to believe information that would run contrary to what the study team believed was in the best interests of the stakeholders. Key among this was the discussion of "protection" and "100-year" storms. Both these concepts have negative outcomes, as the public interprets them. Early attempts at educating the stakeholders on risk led the study team to the recognition that the public would believe themselves to be "protected" from storm events, in the event of various structural plans being implemented, and that the concept of a "100-year level of protection" was guaranteed to result in many members of the public believing that a "100-year" hurricane was only possible 100 years in the future, since "we just had one."

The study team convened a group to re-characterize event frequency, and the risks and consequences of various magnitude events occurring, in terms that everyone in the study area could relate to. Frequency-inundation mapping was developed, to characterize events in terms of their depth, and re-occurrence based on past events the community has suffered, rather than an arbitrary frequency that the public could not understand. Risks and consequences associated with many other factors were also discussed and then re-characterized in simple, easy to understand terms.

The MsCIP team shared this information, through a series of public workshops. These workshops are discussed in greater detail in the Public Involvement Appendix. The key outcome of the initial public workshops, in regards to the education of stakeholders on risk issues, was the better understanding of all the factors involved in the eventuality of either no action, or any number of potential plans, in terms of both human and environmental impacts, risks or probabilities of certain outcomes given certain circumstances, and what that might mean to the individuals concerned, their institutions, and communities.

Education of the stakeholders was understood to be one important part of the process, but requiring additional tools to enlist greater public participation, and expression of stakeholder preferences on plans, in a risk-aware environment. This led to the following step in this process.

PART 4 – RISK INFORMED DECISION FRAMEWORK

Risk-Informed Decision Framework (RIDF) refers to a guided process by which stakeholders can "weigh in" on their preferences, in regards to concepts, measures, and alternative plans, in a manner that leads to group decision-making, at least in regards to stakeholder preferred actions.

The RIDF provides a robust and comprehensive approach toward identifying plans that the public and agencies feel best achieve the particular goals and objectives of that population, and draws from current practice in the fields of multi-criteria decision analysis (MCDA) and risk and uncertainty analysis. The RIDF is solidly grounded in and supports the Corps of Engineers' six-step planning process closely, in augmenting this planning process by incorporating specific techniques and methods from risk analysis and MCDA, to solicit and incorporate public and agency preferences in plan evaluation and selection. RIDF is the logical next step in the process of evaluating and incorporating risk in the planning process, in that it involves the public in the evaluation of potential measures that might be used to address problems, further educates them to the risks and consequences of each potential action, including a No-Action scenario, and allows them to weigh-in on a prioritization process that allows local decision-makers to see what the public desires, and how that might be used in the determination of preferred plans and activities.

The RIDF enhances the level of communication and collaboration among decision-makers and stakeholders by providing structured opportunities for interaction. The RIDF uses the information gained through the initial steps involving the public and agencies to develop a set of factors of importance (referred to as "metrics") in the analysis of specific problems and sites, for which the Study team then develops units of measurement for which to compare each metric later in the process, and solicits publically-, and agency-determined "weights" or preferences that reflect stakeholder priorities. This provides an analytically sound, defensible, and quantitative approach to aid in local decision-making. In this way, decision outcomes can more adequately satisfy the interests, values, and objectives of most importance to the individuals and agencies weighing in on each alternative plan.

Metrics evaluated during the MsCIP RIDF process included measures of the total cost as well as local implementation costs, acres of habitat lost or restored by No-Action or various restoration plan opportunities, potential impacts to physical and mental health, impacts to cultural integrity, regional economic well-being, residual risks and risk of failure of a given plan, and other factors.

The RIDF also incorporated information about uncertainty into the decision process and facilitates discussion of residual risks, which include the expected damages or consequences resulting from events, and which might result even in the event of construction of a large project or implementation of a program. Accurate forecasts about the future are difficult, and decisions that ignore these uncertainties may differ from and perform less well than those that do not. The MsCIP RIDF process also incorporated uncertainty originating from two additional sources of particular importance in this area, those of relative sea level rise (resulting from both global sea level rise and sinking of the land relative to the sea's surface) and the future potential patterns of re-development. Information about these uncertainties manifests itself in the outcome metrics and in the scoring and ranking of alternative plans.

Ultimately, the optimality of a prospective public and agency decision outcome depends upon values and beliefs that can vary across different stakeholder groups. Since the MsCIP decision process involves a broad spectrum of stakeholders, the RIDF evaluates the sensitivity of the recommendations to these values and beliefs to help decision-makers and stakeholders understand the prioritization of factors by any group or individual, and their emotion about each plan and its potential outcomes. Use of RIDF may further help to identify what additional studies may be needed

and what communication and negotiation efforts could be improved. These efforts help to build confidence in the planning process, involve the public and agencies in decision-making, and may enhance commitment to selected alternatives. RIDF also educates and obtains input on the role that adaptive management can play in the long-term outcomes of potential plans, and incorporates public and agency input on monitoring and maintaining the performance of projects and programs over longer planning horizons.

Detailed discussion on the models used, the creation, selection and characterization of metrics used, and the outcome of stakeholder weighting sessions, is contain in the attachment to this appendix.

PART 5 – COMPARISON, SCREENING, AND CONSIDERATION OF RISK, IN THE PLAN SELECTION PROCESS

The Fifth and final phase of Risk Analysis in the MsCIP Study process involved comparison of no-action and alternative plans, in a side-by-side trade-off presentation of plan outcomes, potential inherent and residual risks, associated with various No-Action and with-project scenarios, through display in a System of Accounts format. Screening of alternatives, by use of the System of Accounts tables, and consideration of all apparent risks, uncertainties, potential consequences and outcomes, led to screening of alternatives, weighing of the outcomes of each alternative, and identification, by Stakeholders, of a "Stakeholder-Preferred" (where applicable) Plan, and "Federally-recommended" courses of action for each problem area, based on the best-balance of objective outcomes, achievement of high cost-effectiveness, and inclusion as a key element of a comprehensive package of recommendations, directed at achieving a lower-risk, higher sustainability environment. The goal of this process was to generate a full range of tiered recommendations aimed at achievement of the study objectives, and identification of those measures for immediate or longer-term action as a result of the decision document being acted upon by Congress.

The Accounts displayed and used in this final part of the process, included the standard four accounts identified in the USACE Plan Formulation Guidance: "National Economic Development" (NED), "Regional Economic Development" (RED), "Environmental Quality" (EQ), "Other Social Effects" (OSE). In addition a "Risk" (RISK) account was added to fully identify the inherent risks associated with no action or the implementation of any one of the measures. The System of Accounts tables also display the Stakeholder Preference "scores" resulting from the public and agency RIDF process, as well as a final discussion of the selection result, based on those factors of greatest importance in that selection, for both "Stakeholder", and "Federally-Recommended" actions.

The stakeholder "scores" from the public and agency RIDF process, presented in the System of Accounts tables, resulted from a summary of the most recent series of public/agency workshops, and the application of the multi-criteria decision analysis. The summary of those scores waqs presented as the Stakeholder Preference score, for each of the final array of plans. This number rates each alternative, in concept, as a percentage of a theoretical "perfect plan" (in the eyes of the stakeholder group). The higher the score reflects the stakeholder belief that the alternative provides the best fit to their value judgments of the metrics. In other words, the higher the score, the more acceptable the alternative should be to that stakeholder group.

Because the stakeholders may possess very different life experiences and also may not have possessed full information on the nature and magnitude of potential risks associated with any plan of action, the MsCIP study application of the planning process required that the Corps' study team have ultimate responsibility for a Federally-recommended plan selection, based on full consideration of risk factors and potential consequences of plan implementation. This was determined to be especially important in the consideration of alternatives that had potentially negative outcomes under various future scenarios.

The study team engaged Corps and outside experts, to characterize residual or inherent risks, and to potentially recommend actions based on these over-riding criteria, in meeting the original mission as detailed by the Congress. This final part of the process was considered to be the key final level of input to the planning process, particularly in this high-risk situation.

An example of the evaluation, comparison, and rationale leading identification of plans recommended for implementation, as formulated to deal with a particular problem set at a specific site, is illustrated below, and also provided for each recommendation, within the body of the Main Report.

The Barrier Islands of the Gulf Coast form an important attribute in the system of islands, water bodies and mainland features of the coast of Mississippi. They function as a barrier to saltwater intrusion, maintaining a delicate salinity balance on which many species depend for survival within Mississippi Sound. The barrier islands attenuate wave and surge height. They also provide for a host of unique environmental conditions, both terrestrial and aquatic, and create unique conditions on which mainland values depend. Most of the barrier islands are managed by the National Park Service, with some being designated Wilderness Areas, and protected by stringent regulation.

Analysis of the effects of hurricanes Katrina, Rita, and others indicated a large number of problems caused by their erosion and degradation. Loss of the barrier islands has led to increased salinity within Mississippi Sound, increased potential wave and surge effects within the study area, and loss of aquatic species viability. Degradation of the many functions and values provided by the barrier islands, and their identification as a large focus of study effort, lead to the creation of a large number of potential measures by which restoration of the islands, and protection of resources might be achieved.

Many potential measures would be intrusive, and would violate Wilderness Act protections, due their active interference in natural processes. The list of potential measures was rapidly screened by the joint interagency sub-committee created to evaluate barrier islands options, to a shorter list containing only a No-Action Plan, restoration of the pre-hurricane island footprint plan (Plan A), a sand replenishment plan (Plan C), restoration of Ship Island breach only (Plan G), and a combination plan that would address sand replenishment and repair of Ship Island (Plan H).

Data on costs, benefits (both monetary damages prevented and ecological damages prevented), environmental quality issues, societal effects, “Stakeholder Preference” scores generated during the RIDF stakeholder involvement process, and risk factors assessment, were entered into the System of Accounts table shown below. This information was discussed with stakeholders, ranging from members of the public, to the State, and Federal agencies.

The final phase of risk incorporation in the MsCIP planning process, leading to plan selection for the barrier islands element, began with the side-by-side comparison of No-Action and action plan outcomes, with no one factor taking precedence. Examination of possible outcomes indicated that Plan H appeared to provide the most complete, effective, efficient and acceptable alternative plan. Plan H would achieve a high degree of restoration benefit, at less than half the cost of Plan A, and virtual identical damage reduction and protection of fisheries. It is a more complete solution than plans C or G, particularly in regards to protection of fisheries and restoration of tidal and non-tidal habitat. Plan H also would create positive monetary net benefits, demonstrating its cost-effectiveness (one of the primary charges given by Congress), with damage reduction benefits of approximately $18.8 million annually, protection of fisheries benefits of approximately $44 million annually, and restoration of 456 acres of tidal, and 694 acres of non-tidal habitat. Plan H would provide similar cultural, environmental quality, societal, and community benefits, at a lesser cost than Plan A. Stakeholder preference scores for Plan A and Plan H were almost identical, with Plan H receiving a marginally higher mean score. Evaluation of risks indicate that Plans A and H would provide similar reductions in several risk factors, including reduction of residual damages (primarily to reduction of wave effects on mainland development), will be minimally impacted by relative sea level rise, and have a low risk of failure (of plan outcomes). While no plan provides for significant positive benefits to life and safety, those are not factors that would be influenced strongly by this element of the comprehensive plan, but by others included in the package of recommendations.

Weighing of all considered factors above provided a clear indicator that Plan H provides the best balance, and indeed, the greatest number and magnitude of positive outcomes, of all plans considered, including the No-Action Plan.

System of Accounts table for Barrier Islands

Ecosystem Restoration and Hurricane and Storm Damage Reduction

Problem Area: Barrier Island Restoration, Hancock, Harrison, and Jackson Counties, Mississippi					
Problems ID: Damages suffered by hurricane-induced surge and wave attack; Potential future damages from storm and hurricane events.					
Item	**No Action**	**Plan A**	**Plan C**	**Plan G**	**Plan H**
A. PLAN DESCRIPTION	No Federal Action	Restore Island Footprint	Replenish Sand in Littoral Zone (Off-Shore & Inland River Sand Source)	Restoration of Ship Island Breach	Combination of C + G
B. IMPACT ASSESSMENT					
1. National Economic Development					
a. Beneficial Impacts					
(1) Damages Prevented	$0	$18,866,000	$10,468,000	$7,616,000	$18,866,000
(2) Emergency Costs Avoided	$0				
(3) Recreation	$0	$466,000	$117,000	$466,000	$466,000
(4) Total Beneficial Impacts	None.	$19,332,000	$10,585,000	$8,082,000	$19,332,000
b. Adverse Impacts					
(1) Project Cost	$0	$942,200,000	$147,400,000	$181,400,000	$328,800,000
(2) Interest During Construction	$0	$119,317,000	$18,667,000	$22,972,000	$41,639,000
(3) Average Annual First Cost	N/A	$58,376,000	$9,133,000	$11,239,000	$20,372,000
(4) Annual O&M	$0	$0	$0	$0	$0
(5) Total Avg. Annual Costs	$0	**$58,376,000**	**$9,133,000**	**$11,239,000**	**$20,372,000**
2. Environmental Quality (EQ)					
(1) Ecosystem Restoration	No benefit	Restoration of 644 acres of tidal habitat and 2036 acres of nontidal habitat.	Restoration of 326 acres of tidal habitat and 217acres of nontidal habitat.	Restoration of 130 acres of tidal habitat and 477 acres of nontidal habitat.	Restoration of 456 acres of tidal habitat and 694 acres of nontidal habitat.

Problem Area: Barrier Island Restoration, Hancock, Harrison, and Jackson Counties, Mississippi

Problems ID: Damages suffered by hurricane-induced surge and wave attack; Potential future damages from storm and hurricane events.

Item	No Action	Plan A	Plan C	Plan G	Plan H
(2) Protection of Fisheries	**Loss of $43,618,143** in average annual fishery landings	Avoidance of **$43,618,143** in lost fishery landings.	Avoidance of **$6,542,721** in lost fishery landings.	Avoidance of **$21,809,072** in lost fishery landings.	Avoidance of **$43,618,143** in lost fishery landings.
(3) Water Circulation	Area would become more open Gulf in nature as islands erode	No anticipated effect.	No anticipated effect.	No anticipated effect.	No anticipated effect.
(4) Noise Level Changes	No change in noise levels	Temporary increase in noise levels during construction	Temporary increase in noise levels during construction	Temporary increase in noise levels during construction	Temporary increase in noise levels during construction
(5) Public Facilities	Loss of the barrier islands would result in loss of National Parks	National Parks would be preserved.	National Parks would be enhanced by supplemental sand supply.	National Parks would be enhanced by supplemental sand supply.	National Parks would be preserved.
(6) Aesthetic Values	Continued degradation of aesthetic values	Significant aesthetic improvement	Moderate aesthetic improvement	Moderate aesthetic improvement	Significant aesthetic improvement
(7) Natural Resources	Continued degradation of islands and loss of function of MS Sound.	Significant reduction in loss of island and function of MS Sound.	Minor reduction in loss of island and function of MS Sound.	Moderate reduction in loss of island and function of MS Sound.	Significant reduction in loss of island and function of MS Sound.
(8) Biological Resources	Continued degradation and loss of biological resources.	Significant improvement in biological resources.	Moderate improvement in biological resources.	Moderate improvement in biological resources.	Significant improvement in biological resources.
(9) Air Quality	No anticipated effect on air quality	Air emission would be *de minimus*	Air emission would be *de minimus*	Air emission would be *de minimus*	Air emission would be *de minimus*
(10) Water Quality	Water quality is anticipated to deteriorate with future loss of the island system (salinity increase will decrease size of estuarine zone).	Temporary negative impacts to water quality due to construction but overall long-term improvements to water quality are anticipated.	Temporary negative impacts to water quality due to construction but overall long-term improvements to water quality are anticipated.	Temporary negative impacts to water quality due to construction but overall long-term improvements to water quality are anticipated.	Temporary negative impacts to water quality due to construction but overall long-term improvements to water quality are anticipated.

Problem Area: Barrier Island Restoration, Hancock, Harrison, and Jackson Counties, Mississippi

Problems ID: Damages suffered by hurricane-induced surge and wave attack; Potential future damages from storm and hurricane events.

Item	No Action	Plan A	Plan C	Plan G	Plan H
(11) Public Services	Possible increase in interruption of services as islands continue to erode	Increased stability of barrier islands would reduce likelihood of interruption of public services.	Increased stability of barrier islands would reduce likelihood of interruption of public services.	Increased stability of barrier islands would reduce likelihood of interruption of public services.	Increased stability of barrier islands would reduce likelihood of interruption of public services.
(12) Cultural and Historical Preservation	Alternative would result in future loss of important cultural resources at Ship Island.	Alternative would preserve cultural and historical artifacts, including Fort Massachusetts and the French Warehouse.	Alternative would provide some reduction in impact to cultural and historical artifacts, including Fort Massachusetts and the French Warehouse.	Alternative would preserve cultural and historical artifacts, including Fort Massachusetts and the French Warehouse.	Alternative would preserve cultural and historical artifacts, including Fort Massachusetts and the French Warehouse.
(13) Total Quality of the Environment	Significant negative impact on the total quality of this environment if the islands erode away	Significant positive impacts on the total quality of environment (i.e. future production of Mississippi Sound)	Significant positive impacts on the total quality of environment (i.e. future production of Mississippi Sound)	Significant positive impacts on the total quality of environment (i.e. future production of Mississippi Sound)	Significant positive impacts on the total quality of environment (i.e. future production of Mississippi Sound)
3. Regional Economic Development (RED)					
(1) Impact on Sales Volume	No impact to the local economy.	Increase of **$2,289,546,000** in additional sales volume.	Increase of **$358,182,000** in additional sales volume.	Increase of **$440,802,000** in additional sales volume.	Increase of **$798,984,000** in additional sales volume.
(2) Impact on Income	Negative impact to individuals involved in fishing industry as islands erode and MS Sound environment changes.	Increase of **$480,984,800** in additional local income.	Increase of **$75,246,410** in additional local income.	Increase of **$92,603,120** in additional local income.	Increase of **$167,849,530** in additional local income.

Problem Area: Barrier Island Restoration, Hancock, Harrison, and Jackson Counties, Mississippi

Problems ID: Damages suffered by hurricane-induced surge and wave attack; Potential future damages from storm and hurricane events.

Item	No Action	Plan A	Plan C	Plan G	Plan H
(3) Impact on Employment	Negative impact to individuals involved in fishing industry as islands erode and MS Sound environment changes.	Increase of **14,100** new jobs.	Increase of **2,206** new jobs.	Increase of **2,714** new jobs.	Increase of **4,920** new jobs.
(4) Tax Changes	Possible negative impacts as islands erode and chance of storm damage increases	None	None	None	None
4. Other Social Effects (OSE)					
a. Beneficial Impacts					
(1) Security of Life, Health, and Safety	Continued risks to life, health and safety	Significant decrease in risks to life, health and safety.	Moderate decrease in risks to life, health and safety.	Moderate decrease in risks to life, health and safety.	Significant decrease in risks to life, health and safety.
(2) Community Cohesion	Negative impacts as islands continue to erode and damages from waves and storms increase above the existing level.	Positive impact as community observes coastal resources being restored and stability of barrier islands and MS Sound increased.	Positive impact as community observes coastal resources being restored and stability of barrier islands and MS Sound increased.	Positive impact as community observes coastal resources being restored and stability of barrier islands and MS Sound increased.	Positive impact as community observes coastal resources being restored and stability of barrier islands and MS Sound increased.
(3) Tax Values	Negative impacts as islands erode and chance of storm damage increases	Moderate increase in tax values due to decreased risk to properties.	Small increase in tax values due to decreased risk to properties.	Small increase in tax values due to decreased risk to properties.	Moderate increase in tax values due to decreased risk to properties.

Problem Area: Barrier Island Restoration, Hancock, Harrison, and Jackson Counties, Mississippi

Problems ID: Damages suffered by hurricane-induced surge and wave attack; Potential future damages from storm and hurricane events.

Item	No Action	Plan A	Plan C	Plan G	Plan H
(4) Community Growth	Could have negative impact on growth as islands continue to erode	Moderate positive impact to community growth	Small positive impact to community growth	Small positive impact to community growth	Moderate positive impact to community growth
(5) Property Values	Negative impacts as islands erode and chance of storm damage increases	Moderate increase in property values due to decreased risk to properties.	Small increase in property values due to decreased risk to properties.	Small increase in property values due to decreased risk to properties.	Moderate increase in property values due to decreased risk to properties.
(6) Displacement of Businesses	Potential impacts to businesses from increased risk of surge damage.	Reduced risk of displacement of businesses.	Reduced risk of displacement of businesses.	Reduced risk of displacement of businesses.	Reduced risk of displacement of businesses.
(7) Public Facilities	Negative impacts to public facilities from increased risk of surge damage.	Reduced risk to public facilities.	Reduced risk to public facilities.	Reduced risk to public facilities.	Reduced risk to public facilities.
(8) Injurious Displacement of Farms	N/A	N/A	N/A	N/A	N/A
b. Preservation of life	Not anticipated to contribute to loss of life.	Not anticipated to contribute to loss of life.	Not anticipated to contribute to loss of life.	Not anticipated to contribute to loss of life.	Not anticipated to contribute to loss of life.
C. PLAN EVALUATION					
1. Contributions to Planning Objectives					
a. Flood, Hurricane and/or Storm Damage Reduction	Increased risk in damage reduction from further degradation of islands.	Significant avoidance of increased risk.	Minor avoidance of increased risk.	Moderate avoidance of increased risk.	Significant avoidance of increased risk.

Problem Area: Barrier Island Restoration, Hancock, Harrison, and Jackson Counties, Mississippi

Problems ID: Damages suffered by hurricane-induced surge and wave attack; Potential future damages from storm and hurricane events.

Item	No Action	Plan A	Plan C	Plan G	Plan H
b. Recovery of lost environmental resources	Alternative will result in continued loss of environmental resources.	Barrier Island restoration will accrue unquantified benefits.	Barrier Island restoration will accrue unquantified benefits.	Barrier Island restoration will accrue unquantified benefits.	Barrier Island restoration will accrue unquantified benefits.
2. Response to Planning Constraints					
a. Avoid environmental impacts and minimize induced damages	Continued loss of pre-Katrina environmental resources.	Beneficial effect on environmental resources.	Beneficial effect on environmental resources.	Beneficial effect on environmental resources.	Beneficial effect on environmental resources.
b. Institutional Acceptability	Is not supported by state or local government	Is supported by local and state governments	Is supported by local and state governments	Is supported by local and state governments	Is supported by local and state governments
3. Response to Evaluation Criteria					
a. Acceptability	NO	No, does not meet all Federal policies and regulations (i.e. Wilderness Act)	YES	YES	YES
b. Completeness	NO	YES	NO, it does not avoid all of the future degradation.	NO, it does not avoid all of the future degradation.	YES
c. Effectiveness	NO	YES	NO, not a completely effective solution.	NO, not a completely effective solution.	YES
d. Efficiency (Cost-Effectiveness; i.e., most efficient use of Federal and Non-Federal Funds)	NO	No, over 2 1/2 times as expensive as plan H	No, less efficient than plan A and H.	No, less efficient than plan A and H.	YES, most efficient / cost effective plan.
e. Integration	N/A	Seamless addition to system.	Seamless addition to system.	Seamless addition to system.	Seamless addition to system.

Problem Area: Barrier Island Restoration, Hancock, Harrison, and Jackson Counties, Mississippi

Problems ID: Damages suffered by hurricane-induced surge and wave attack; Potential future damages from storm and hurricane events.

Item	No Action	Plan A	Plan C	Plan G	Plan H
f. Reversibility	This issue does not apply	Alternative could be reversible, given means to remove sand.	Alternative could not be reversible, given placement in open-water.	Alternative could be reversible, given means to remove sand.	A portion of this alternative could not be reversible, given placement in open-water.
4. Stakeholder Preference Score (From MCDA weightings analysis)					
a. Summary Score	**15.53%**	**71.69%**	**62.28%**	**41.70%**	**72.03%**
Cluster Group A	27.16%	67.62%	63.08%	47.53%	73.93%
Cluster Group B	18.82%	70.58%	63.58%	45.57%	73.93%
Cluster Group C	11.83%	74.03%	63.92%	41.81%	73.58%
Cluster Group D	4.30%	74.51%	58.55%	31.90%	66.66%
b. Stakeholder Preference	All groups ranked this plan lowest	Plan ranked very high, but less than H.	Plan ranked lower than A and H.	Plan ranked lowest of all action plans.	Plan ranked highest overall
D. Implementation Responsibility	Does not have any implementation responsibilities	Elements would be joint Federal/Non-Federal implementation responsibility.	Elements would be joint Federal/Non-Federal implementation responsibility.	Elements would be joint Federal/Non-Federal implementation responsibility.	Elements would be joint Federal/Non-Federal implementation responsibility.
E. State and other Non-Federal Coordination	Would require no State or other Non-Federal coordination activities	Would require significant State or other Non-Federal coordination activities	Would require significant State or other Non-Federal coordination activities	Would require significant State or other Non-Federal coordination activities	Would require significant State or other Non-Federal coordination activities
F. Risk Evaluation					
1. Risk and Vulnerabilities					
a. Risk of Failure	N/A	Low	Moderate	Moderate	Low

Problem Area: Barrier Island Restoration, Hancock, Harrison, and Jackson Counties, Mississippi

Problems ID: Damages suffered by hurricane-induced surge and wave attack; Potential future damages from storm and hurricane events.

Item	No Action	Plan A	Plan C	Plan G	Plan H
b. Residual Risk	All barrier islands will overtop during large surge events, and will not provide significant reduction of surge and waves.	All barrier islands will overtop during large surge events, and will not provide significant reduction of surge. Plan A would provide a significant reduction to waves.	All barrier islands will overtop during large surge events, and will not provide significant reduction of surge and waves.	All barrier islands will overtop during large surge events, and will not provide significant reduction of surge and waves.	All barrier islands will overtop during large surge events, and will not provide significant reduction of surge. Plan A would provide a moderate reduction to waves.
c. Reliability	N/A	Plan A would provide a moderate level of reliability, would be resistant to damage from storm events, and would not require significant maintenance.	This plan would provide a low level of reliability, would receive damage from storm events, and would require significant maintenance.	This plan would provide a low level of reliability, would receive damage from storm events, and would require significant maintenance.	Plan A would provide a moderate level of reliability, would be resistant to damage from storm events, and would not require significant maintenance
d. Relative Sea Level Rise	Problems will be substantially exacerbated by an increasing relative rise of sea level	This Plan will be minimally impacted by an increasing relative rise of sea level over the period of analysis	This Plan will be moderately impacted by an increasing relative rise of sea level over the period of analysis	This Plan will be moderately impacted by an increasing relative rise of sea level over the period of analysis	This Plan will be minimally impacted by an increasing relative rise of sea level over the period of analysis
e. Risk of Ecosystem Damage	Ecosystem damage will continue to accrue at a rate at least that of recent history with substantial negative	Risk of ecosystem damage will be minimal throughout the period of analysis.	Risk of ecosystem damage will be moderate throughout the period of analysis.	Risk of ecosystem damage will be moderate throughout the period of analysis.	Risk of ecosystem damage will be minimal throughout the period of analysis.

Problem Area: Barrier Island Restoration, Hancock, Harrison, and Jackson Counties, Mississippi

Problems ID: Damages suffered by hurricane-induced surge and wave attack; Potential future damages from storm and hurricane events.

Item	No Action	Plan A	Plan C	Plan G	Plan H
	outcomes.				
f. Risk to Life and Safety	Significant threats to Life and Safety from storm surge will continue to rise due to continued deterioration of the Barrier Islands.	Significant threats to Life and Safety from storm surge will still exist, but this plan will provide the least risk to life and safety.	Significant threats to Life and Safety from storm surge will still exist, but this plan will provide less risk to life and safety than the No Action Plan.	Significant threats to Life and Safety from storm surge will still exist, but this plan will provide less risk to life and safety than the No Action Plan and Plan C.	Significant threats to Life and Safety from storm surge will still exist, but this plan will provide the least risk to life and safety, except for Plan A.
g. Risk to Mental and Physical Health	Significant threats to Mental and Physical Health from storm surge will continue to rise due to continued deterioration of the Barrier Islands.	Significant threats to Mental and Physical Health from storm surge will still exist, but this plan will provide the least risk to Mental and Physical Health.	Significant threats to Mental and Physical Health from storm surge will still exist, but this plan will provide less risk to Mental and Physical Health than the No Action Plan.	Significant threats to Mental and Physical Health from storm surge will still exist, but this plan will provide less risk to Mental and Physical Health than the No Action Plan and Plan C.	Significant threats to Mental and Physical Health from storm surge will still exist, but this plan will provide the least risk to Mental and Physical Health, except for Plan A.
2. Recommendations and Preferences					

Problem Area: Barrier Island Restoration, Hancock, Harrison, and Jackson Counties, Mississippi

Problems ID: Damages suffered by hurricane-induced surge and wave attack; Potential future damages from storm and hurricane events.

Item	No Action	Plan A	Plan C	Plan G	Plan H
a. Federal Recommendation					This Plan has the highest NED benefits, substantial RED benefits, substantial EQ benefits, the greatest achievement of OSE outcomes, does not violate any local, state, or Federal statues, laws, and regulations, and is the most cost effective and efficient recommendation of the Barrier Island component of the Comprehensive Plan
b. Stakeholder Preference					This Plan has the highest stakeholder preference score, and creates a low risk environment.

GLOSSARY

Cluster: A set of data that share a common trait.

Eustatic: Changes in sea-level that are caused by global forces such as climate change.

Isostatic: Changes in sea-level that are caused by local forces such as land subsidence and glacial rebound.

Measure: A component of plans for risk reduction. Categories of risk reduction measures include structural, non-structural and coastal restoration.

Metric: A parameter for quantifying the performance of plans in respect to planning objectives.

Natural variability: The heterogeneity of some attribute in a population.

Plan: Any detailed scheme, program, or method worked out beforehand to accomplish an objective. A plan could incorporate structural, non-structural, and/or coastal restoration measures or combination of measures for risk reduction. Plans emerge from the plan formulation process.

Residual risk: The portion of risk remaining after the recommended plan has been implemented.

Risk: Risk is fully defined by an event probability, a set of factors on which that event probability is conditioned (scenarios), and the consequences of that event.

Uncertainty: A lack of knowledge that originates from an incomplete understanding of the structure and function of natural or manmade systems, the choice of a model to represent those systems, and the choice of the input values for the parameters of the chosen model.

Variance: A measure of statistical dispersion, averaging the squared distance of its possible values from the expected value (mean). Variance captures the mean's scale or degree of being spread out.

EXECUTIVE SUMMARY

This part of the Risk Appendix outlines a Risk-Informed Decision Framework (RIDF) for the Mississippi Coastal Improvements Program (MsCIP) effort. The RIDF provides a robust and comprehensive approach toward identifying plans that the public and agency stakeholders feel best achieve the particular goals and objectives of that population and draws from current practice in the fields of multi-criteria decision analysis (MCDA) and risk/uncertainty analysis. The RIDF is solidly grounded in and follows closely the Corps of Engineers six-step planning process closely, but augments this planning process by incorporating specific techniques and methods from risk analysis and MCDA. There are numerous advantages to this approach.

The RIDF enhances the level of communication and collaboration among decision-makers and stakeholders by providing structured opportunities for interaction. The RIDF uses the information gained through this process to define a set of decision objectives, outcome metrics, and preference weights that reflect stakeholder priorities and provide an analytically sound, defensible, and quantitative approach to decision making. In this way, decision outcomes can more adequately satisfy the interests, values, and objectives germane to the decision. The RIDF also incorporates information about uncertainty into the decision process and facilitates discussion of residual risks, which are the expected damages from storms that will remain after a storm defense is built. Accurate forecasts about the future are difficult, and decisions that ignore these uncertainties may differ from and perform less well than those that do not. Therefore, the RIDF explicitly considers uncertainty originating from two sources including relative sea level rise and the future pattern of development. Information about these uncertainties manifests itself in the outcome metrics and in the scoring and ranking of alternative plans.

The optimality of a prospective decision outcome depends upon values and beliefs that can vary across different stakeholder groups. Since the MsCIP decision process involves a broad spectrum of stakeholders, the RIDF evaluates the sensitivity of the recommendations to these values and beliefs to help decision-makers and stakeholders understand the robustness of recommendations and anticipated outcomes. In this way, the RIDF helps to identify what further studies may be needed and what communication and negotiation efforts could be improved. These efforts also build confidence in the planning process and commitment to the selected plans. We also recognize the role that adaptive management can play in connection with the RIDF as a mechanism for monitoring and maintaining the performance of decisions over longer planning horizons.

1. INTRODUCTION

1.1 Background

This report summarizes the results of a risk-informed decision framework (RIDF) as applied in the Mississippi Coastal Improvements Project (MsCIP) as part of the development of a comprehensive plan to reduce the residual risks from flood and storm surge inundation and coastal wetlands loss and degradation. The intent of the RIDF is to "**develop a decision framework in such a manner as to simply and clearly show to decision makers and the public the risks, costs and consequences of flood control, coastal restoration, and hurricane protection measures...[and] recommendations…will be supported…using the risk informed decision framework.**"

A comprehensive plan addresses a full range of risks to people, environment, property, and economy as well as infrastructure construction, operations, and maintenance costs. Risk is fully defined by an event probability, a set of factors on which that event probability is conditioned (scenarios), and the consequences of that event (Kaplan and Garrick 1981). With respect to flood risk management, residual risk has been defined by the National Research Council (2000) as that risk that remains after a flood damage reduction project is implemented.

This part of the Risk Appendix develops the risk-informed decision framework (RIDF). The RIDF has been developed by the Engineer Research and Development Center (ERDC) to integrate risk and decision science methods into the US Army Corps of Engineers (USACE) planning process while emphasizing consistency with existing USACE planning guidance.

The MsCIP decision process must consider a comprehensive set of planning objectives that include: 1) the reduction of risks to human life, property, and the regional economy; 2) the protection of the region's natural resources, and environmental quality; and 3) the construction, operations, and maintenance costs associated with any particular alternative. In addition to these numerous diverse interests that must be addressed through the planning process, the Mississippi coastal area is a dynamic environment that is rapidly changing in ways that are difficult to predict. Prudent decision makers will therefore take account of the uncertainty regarding economic, environmental, and other conditions that may affect the outcome of a project during the planning horizon.

The MsCIP decision problem is to recommend a comprehensive plan that will reduce the risks of flooding caused by storm surge and coastline degradation while considering a full range of risks to people, environment, property, and economy as well as infrastructure construction, operations, and maintenance costs. The RIDF is responsive to these and other decision support needs of MsCIP for which conventional decision support methods are poorly suited. The RIDF offers a decision approach that accounts for a comprehensive set of coastal assets in Mississippi and acknowledges the presence of a diverse group of stakeholders who exhibit conflicting interests and objectives. The RIDF approach also addresses uncertainty in certain environmental, social, and economic trends over the planning horizon that can affect the desirability of risk reduction strategies.

Conventional approaches to decision making have emphasized cost-benefit analysis, which is suitable only when decision outcomes can be fully monetized. There is now an increasing level of

consideration given to assets that are difficult to quantify in economic terms, such as wildlife habitat and cultural diversity, and tend to confound the application of that approach. Conventional decision methods have also emphasized a single decision objective built around national economic development objectives. However, the MsCIP planning guidance requires an accounting of regional economic development, environmental, and other social effects objectives as well. Therefore, a multi-attribute decision analysis method is needed. In addition to presence of multiple objectives, there is diverse set of stakeholders whose interests must also be taken into account. Conventional approaches to decision making have also tended to ignore uncertainty. By evaluating and communicating uncertainty during the planning process, RIDF helps lead decision makers to more well-reasoned and rational choices. The RIDF attempts to addresses all of the shortcomings of conventional decision approaches in a manner that is consistent with the USACE planning guidelines.

1.2 Overview of the Risk-Informed Decision Framework

1.2.1 RIDF is based on the Corps Planning Process, Outfitted to Incorporate Risk Analysis and Decision Analysis

The Risk-Informed Decision Framework (RIDF) is rooted in the Corps' standard approach to planning, but augments that approach with insights and techniques drawn from the fields of decision and risk analysis. RIDF provides procedures to help decision makers identify planning objectives, performance metrics, and stakeholder priorities.

RIDF draws on multi-criteria decision analysis (MCDA) techniques (specifically, multi-attribute utility theory (MAUT), because plan selection involves multiple, competing objectives denominated in in-commensurate terms. For example, this is the case when some attributes of an objective such as life-cycle infrastructure costs can be expressed in monetary terms and others, such as environmental quality, cannot.

RIDF draws on risk analysis (RA) techniques to characterize and assess the uncertainties that complicate the MsCIP decision. These include uncertainties in the economic and environmental conditions that will influence the outcome of a decision (such as the rate of sea-level rise) as well as the stochastic nature of storm surge events. The objective is to help planners characterize the critical uncertainties most important to the choice among plans and to identify robust risk reduction strategies, which are decision alternatives that perform relatively well across a wide range of future conditions.

1.2.2 Why is RIDF "Risk-Informed?"

RIDF is risk-informed because it:

- accounts for the consequences of low-probability storms including expected property damages, population at risk, and regional economic impacts.

1.2.3 What are the Advantages of RIDF?

The RIDF has several advantages.

- The framework engages stakeholders and decision makers in a process of issue identification and priority setting to formally establish project goals. The process helps decision makers to:
    - Identify and reveal hidden agendas
    - Identify, acknowledge and, when possible, fill data gaps that, if filled, could influence decisions;
- Objectives are expressed in the form of a multi-attribute utility function that:
    - gives objectives that are difficult to monetize the same consideration as monetary objectives, enabling environmental and social decision objectives to receive equal consideration with economic objectives.
    - allows decision makers to make explicit tradeoffs between objectives because progress on one objective can be used to compensate for lack of progress on another objective.

1.3 Scope of Risk Informed Decision Framework

Part 2 of the Risk Appendix provides an overview of the six planning steps in terms of the MsCIP risk-informed decision framework including:

- Introduction, background and scope
- Methods used to implement MCDA and the RIDF
- Detailed descriptions of metrics and scenarios
- Results of rankings and uncertainty
- Discussion
- Tables and figures showing outputs

2. BACKGROUND

2.1 Planning in the USACE – The Six-Step Planning Process

The *Economic and Environmental Principles and Guidelines for Water and Related Land Resources Implementation Studies* (also known as Principles and Guidelines or P&G) and Engineering Regulation (ER) 1105-2-100, *Guidance for Conducting Civil Works Planning Studies* sets out a six-step planning process:

1. Specify problems and opportunities;
2. Inventory, forecast and analyze conditions relevant to the identified problems and opportunities;
3. Formulate alternative plans;
4. Evaluate the effects of the alternative plans;
5. Compare alternative plans;
6. Recommend a plan from the compared alternatives.

Since publication of the P&G in 1983, U.S. Army Corps of Engineers (USACE) planning and decision-making have been based, primarily, on a comparison of alternatives using economic factors (USACE 2003a). Planners have also been confronted with the challenge to provide for integrated systems that serve multiple objectives (e.g., a coastal system that provides for flood and storm damage reduction, navigation, and ecosystem restoration).

2.2 Changes to the Planning Landscape

In response to a USACE request for a review of P&G planning procedures, the National Research Council (1999) provided recommendations for streamlining planning processes, revising P&G guidelines, analyzing cost-sharing requirements and estimating the effects of risk and uncertainty integration in the planning process. Implementation guidance of the Environmental Operating Principles (EOP) (http://www.hq.usace.army.mil/cepa/envprinciples.htm) within USACE civil works planning directs that projects adhere to a concept of environmental sustainability that is defined as “a synergistic process whereby environmental and economic considerations are effectively balanced through the life of project planning, design, construction, operation and maintenance to improve the quality of life for present and future generations” (USACE 2003a). While adhering to the overall P&G methodology, USACE (2003b) advises project delivery teams to formulate acceptable, combined economic development/ecosystem restoration alternatives through use of multi-criteria/trade-off methods.

2.3 Corps Efforts to Address Planning Needs

Over the last several years, the Corps has been developing approaches and guidance for implementing multi-criteria decision analysis (MCDA) approaches for planning (Yoe, 2002; Linkov et al. 2004; Kiker et. al. 2005). This approach utilizes a comprehensive decision analytic framework that considers a broad array of objectives and criteria/metrics, including those associated with ecosystem restoration (Males, 2002). Guidance contained in *Trade-Off Analysis Planning and Procedures Guidebook (2002)* lays out a multi-criterion decision analytic approach for comparing and deciding between alternative plans and relates the P&G six-step planning process described above to outputs of the RIDF, as depicted in Figure 2-1.

Over the last several years, the Corps has been developing approaches and guidance for implementing multi-criteria decision analysis (MCDA) approaches for planning (Yoe, 2002; Linkov et al. 2004; Kiker et. al. 2005). The challenge has been to select and implement an analytical approach that best serves the Corps' needs and provides outputs that can be incorporated into existing decision-making processes, which is laid out in the Corp's *Trade-Off Analysis Planning and Procedures Guidebook (2002)*. In addition to serving the needs of Corps planning, the decision framework should provide structure and tools for interacting and communicating with partners, stakeholders, and the public about planning and risk. The approach utilizes a comprehensive decision analytic framework that considers a broad array of objectives and criteria/metrics, including those associated with ecosystem restoration (Males, 2002).

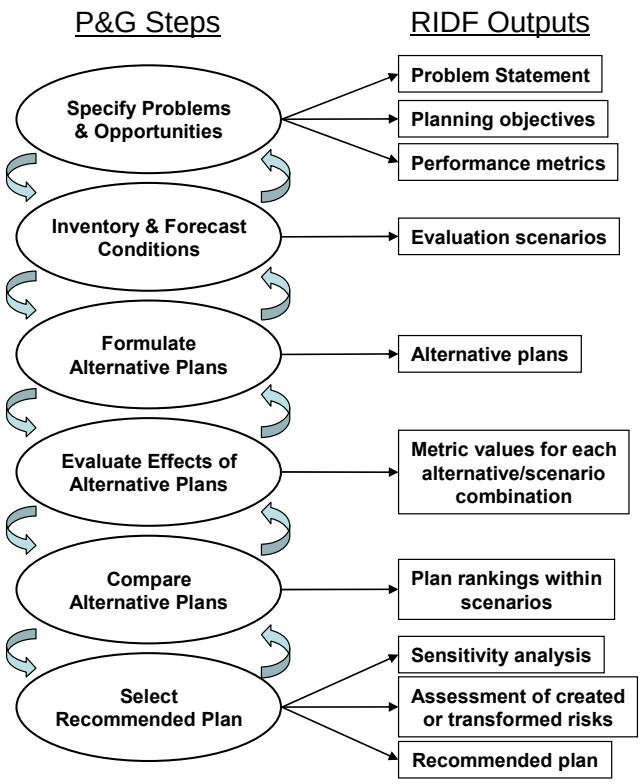

Figure 2-1: The 6 steps of the P&G and resultants outputs of the risk-informed decision framework.

2.4 How is RIDF an Incremental Improvement in Addressing Planning Needs?

Making effective and credible flood and storm damage reduction planning decisions requires an explicit structure for jointly considering the positive/negative impacts and risks, along with associated uncertainties, relevant to the selection of alternative plans. The complexity of flood and storm damage reduction and coastal landscape stabilization in south Mississippi requires integration of multiple models and tools as well as expert judgment. Integrating this heterogeneous and uncertain information demands a systematic and understandable framework to organize complex and often limited technical information and expert judgment.

Having the right combination of ***people*** is the first essential element in the decision process. The activity and involvement levels of three basic groups of people (decision makers, scientists and engineers [e.g., the MsCIP technical team], and stakeholders) are symbolized in Figure 2 by dark lines for direct involvement and dotted lines for less direct involvement. While the actual membership and function of these three groups may overlap or vary, the roles of each are essential in maximizing the utility of human input into the decision process. Each group has its own way of

viewing the world, its own method of envisioning solutions, and its own societal responsibility. Policy- and decision-makers spend most of their effort defining the restoration planning context and the overall constraints on the decision. In addition, they may have responsibility for final plan selection and implementation. Scientists and engineers, including the MsCIP technical team, have the most focused role in that they provide the measurements for metrics that quantify the degree to which the various alternatives satisfy the objectives of the project; while they may take a secondary role as stakeholders or decision-makers, their primary role is to provide the technical input necessary to inform the decision process. Stakeholders contribute the most input in helping formulate performance metrics and making value judgments for weighting the various metrics. Depending on the problem and restoration context, stakeholders may have some responsibility in ranking and selecting the final option.

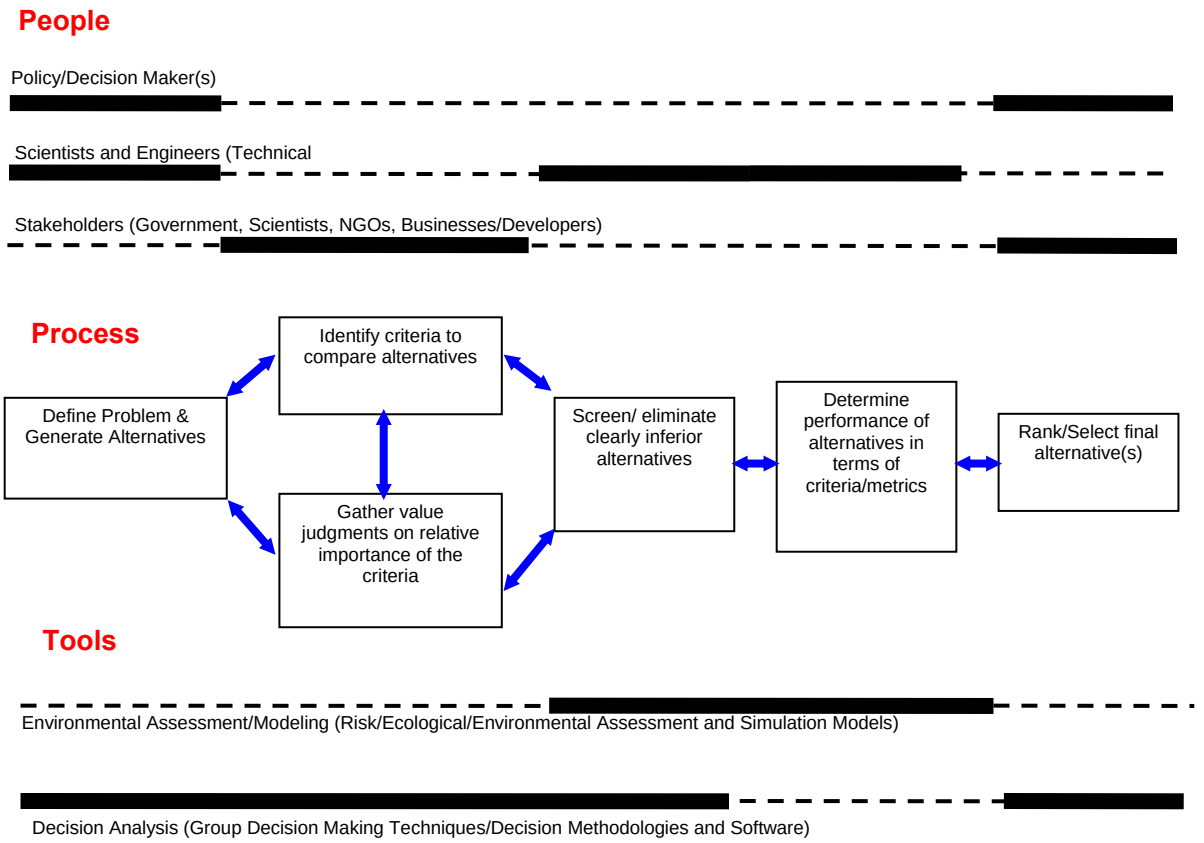

Figure 2-2: Proposed decision process (adapted from Linkov et al. 2004 and Kiker et al. 2005). Dark lines indicate direct involvement / applicability and dotted lines indicate less direct involvement / applicability.

The ***process*** depicted in Figure 2-2 is composed of two major elements: (i) generating alternative restoration scenarios, performance metrics, and value judgments and (ii) ranking the alternatives by applying value weights. The process generates and defines choices, performance levels, and preferences. The process also methodically screens non-feasible alternatives by first applying

screening mechanisms (*e.g.*, excessive cost, performance below minimal levels or unacceptable social consequences) and then evaluating, in detail, the remaining alternative restoration plans through the use of decision criteria/metrics that are parameterized with data from engineering models, experimental data, or expert judgment and then ranking those plans through use of MCDA techniques. MCDA separates out judgments about scaling the relative performance of alternatives using a metric from judgments about weighting those metrics (Clemen, 1995). We discuss scaling and weighting in subsection 3.5.1. While it is reasonable to expect that the process may vary in specific details for different planning projects (i.e., based on project needs), the planning accomplished through use of this framework operates within an overall adaptive management structure whereby learning, accomplished through additional study and monitoring, is being used to ensure that the process is responsive to changes in decision priorities or new knowledge that can affect alternative selection or implementation strategies.

The ***tools*** used within group decision making and scientific research are essential elements of the overall decision process. The applicability of the tools is symbolized in Figure 2-2 by solid lines (direct involvement) and dotted lines (indirect involvement). Decision analysis tools help to generate and map technical data as well as individual judgments into organized structures that can be linked with other technical tools from risk analysis, modeling, monitoring, and cost estimations. Decision analysis tools can also provide useful graphical techniques and visualization methods to express the gathered information in understandable formats. When changes occur in the requirements or the decision process, decision analysis tools can respond efficiently to the new inputs. Flood and storm damage reduction planning requires the use of multiple mechanistic, empirical, and stochastic models, and combinations thereof, for examining flood and storm inundation stage-frequencies to assess the performance of alternatives under several uncertain future conditions. Output from these models has been combined to calculate specific risk factors affecting coastal Mississippi. Finally, decision models incorporated individual risk model predictions and reconciled conflicting priorities expressed by different stakeholder groups through transparent and reproducible valuation protocols. The decision analysis tools were used to compare the alternative plans and conduct sensitivity analysis to assess the robustness in relative performance across future scenarios of the resulting rankings.

The entire process results in a comprehensive, structured process for selecting the optimal alternative in any given situation, drawing from stakeholder preferences and value judgments as well as scientific modeling and risk analysis.

2.5 Adaptive Management

The consequences of Hurricane Katrina have motivated the Corps to examine both its processes and institutional culture. The Corps' must be responsive and reliable, and change will be required to ensure that Corps remains so. Actions for Change were identified that will serve as catalysts for that change (see http://www.hq.usace.army.mil/cepa/releases/News_Release_-_USACE_12_Actions_for_Change.pdf). Key to the successful implementation of these actions is use of integrative and comprehensive systems-based approaches, adaptive planning, stakeholder involvement and risk communication.

3. IMPLEMENTATION OF THE RIDF

The Risk-Informed Decision Framework (RIDF) assists decision makers by condensing the decision process into a transparent and tractable format. RIDF can be described in terms that are closely aligned with the standard Corps approach to planning, but utilizes techniques from the fields of risk and decision analysis to accommodate multiple objectives, conflicting stakeholder values, both qualitative and quantitative assessments of performance, and uncertainty in the natural, social, and economic environment in which decisions will be played out.

As implemented for MsCIP, the RIDF procedure can be summarized as follows. Decision makers and stakeholders establish an objectives hierarchy to fully and uniquely characterize the important outcomes of each decision alternative. A set of outcome measures of performance is then chosen to represent the performance of each alternative in terms of achieving each of the decision objectives. The outcomes of the alternative plans is modeled and, to the extent there are uncertainties present that may significantly affect performance outcomes, this evaluation of plans would be replicated over a set of scenarios that represent a range of possible conditions during the performance phase. Once all of these evaluations are complete, a multi-attribute utility function is developed to assess the overall utility of each plan given its performance in terms of achieving the objectives.

The relationship between the six steps of the Corps planning process and RIDF is illustrated in Figure 2-1. In general, RIDF activities are closely related to the six step Corps planning process as follows:

1. Specify Problems & Opportunities: Frame the decision by developing a problem statement and identifying the spatial and temporal boundaries of analysis. Establish planning objectives and choose outcome measures of performance, or metrics, which reflect progress toward achieving the planning objectives.

2. Inventory and Forecast Conditions: Select models of physical and economic systems or other appropriate tools to simulate decision outcomes in terms of the selected performance metrics. Identify important sources of uncertainty in physical and economic models.

3. Formulate Alternative Plans: Formulate decision alternatives by identifying potential measures for flood risk reduction and environmental restoration, pre-screening infeasible measures, and formulating coast-wide plans from remaining measures.

4. Evaluate Effects of Alternative Plans: Model the outcome measures of performance for each alternative and each scenario.

5. Compare Alternative Plans: Obtain weights on objectives from the decision maker and/or stakeholder groups. Calculate multi-attribute utility and implement the decision analysis for each alternative, each scenario, and each stakeholder group. Screen out plans that are consistently dominated.

6. Select a Recommended Plan: Develop recommendations based on the analysis.

3.1 Step 1: Specify the problem and opportunities

Framing the problem to be solved is often one of the most difficult and critical tasks in the planning process because it forces planners to clarify their objectives. Framing also helps to identify what attributes should be considered in judging decision outcomes and what metrics should be used in assessing progress toward objectives. Framing helps to establish what spatial and temporal scales are needed for modeling decision outcomes. For example, the preferred alternative may change with the spatial resolution chosen for an analysis; therefore, factoring such spatial variation into how the framework is used along the coast should be considered. Similarly, the most preferred decision may vary as a function of the timeframe under consideration: a longer planning timeframe may lead to a preference for alternatives with higher fixed costs and lower operational/maintenance costs.

3.1.1 Problem Statement

Catastrophic impacts of the 2005 Atlantic Tropical Cyclone season in the Gulf of Mexico identified the need for investment in flood and storm damage risk reduction and coastal ecosystem restoration.

Traditional investigation methods were recognized as insufficient to identify plans for action in averting future disasters directly impacting major metropolitan centers, strategic regional national assets, and significant coastal resources located in south Mississippi. A new planning methodology based on risk and uncertainty would be required to augment traditional approaches, addressing direct adverse impacts as well as large indirect adverse effects of coastal disasters in Mississippi on the rest of the United States. A multi-objective, long range, comprehensive system-scale analysis is needed to identify a full range of measures for risk reduction and coastal landscape stabilization in the event of moderate/frequent and severe/rare storms.

The following problem statement was drafted with the above issues in mind: The people, economy, environment, and culture of coastal Mississippi, as well as the Nation, are at risk from severe and catastrophic hurricane storm events as manifested by:

1. Storm impacts to residential, public, and commercial infrastructure.
2. Storm impacts to people's quality of life.
3. Habitats damaged by saltwater intrusion.
4. Storm-caused erosion of coastal shoreline.
5. Degradation of fish and wildlife habitats that support an array of commercial and recreational activities coast wide.

The risks associated with the problem can rarely be eliminated or entirely prevented. Thus, residual risk remains and must be considered. The nature of the risks to the planning area is identified in the problem statement.

3.1.2 Planning Objectives

The purpose of this section is to delineate the objectives appropriate to a sound solution to the MsCIP decision problem that can be readily articulated to an array of audiences.

As a group, a good set of planning objectives must be collectively exhaustive. That is, nothing that really matters can be left out. However, and again with an eye to simplification, the list must be limited to only the ones that really do matter. A hierarchical arrangement of objectives (e.g., a principal objective branching to a tier or two of sub objectives) is often useful for structuring a complex decision. Each objective should be specific and succinct (Keeney and Raffia 1976). An objective must be unambiguous yet still succinctly stated, as brevity helps communication and clarifies thinking. Each objective must be amenable to measurement using one or a few metrics so that predictions can be quantified and performance ultimately can be assessed. Simultaneously, objectives must be realistically achievable and relevant. Finally, there must be concordance with practical time frames (Hobbs and Meier 2000). In other words, predictions must be possible within the planning time frame or monitoring of performance must be possible within a useful time frame.

The planning objectives for MsCIP are:

- Reduce risk to public health and safety from catastrophic storm inundation;
- Reduce storm damages to infrastructure from catastrophic storm inundation;
- Restore and protect upland and tidal wetland habitats, and;
- Reduce residual risk from catastrophic storm damage.

The objectives identified in the preceding paragraph were organized within the RIDF framework using the USACE P&G System of Accounts (Yoe and Orth 1996), which guides an evaluation of the effects of a project with respect to National Economic Development (NED), Regional Economic Development (RED), Environmental Quality (EQ), and Other Social Effects (OSE). Establishing the system of accounts 1) shows all effects important to decision-making, 2) explicitly shows the NED effects as the basis for establishing the economic feasibility of the plan, 3) offers a rational, organized framework for presenting the results of the MsCIP analysis, and 4) provides a means for comparing plan effects. The plans' effects presented in the system of accounts relate to the plans' contributions toward planning objectives. The effects of the plans are arranged such that the differences among the plans are easily discerned.

In recent history, USACE planners have been guided to select the NED plan (the one maximizing national economic development benefits) as the preferred alternative, while still meeting National Environmental Policy Act requirements. The Mobile District has received slightly different and more flexible guidance for the critical MsCIP project. Namely, choice is not constrained to an NED plan but rather more broadly to a cost-effective plan that best meets objectives across the NED, RED, EQ, and OSE accounts. Metrics proposed in the subsequent section for evaluating project effects in MsCIP are categorized according to these four accounts.

3.1.3 Outcome Metrics of Performance

Metrics to be used to guide the MsCIP evaluation are presented in Table 1A-1E. These metrics were used to score and then rank flood and storm damage reduction and environmental restoration measures and plans. In selecting this set of metrics, we strove to represent the best available information for evaluating alternatives in the MsCIP, keeping in mind the characteristics of effective metrics (see Roy, 1985; Seager et al. 2007, Graedel and Allenby 2002, Seager and Theis 2004; Yoe 2002). Effective metrics are:

- **Comprehensive and complete:** The metric set should capture the entire range of the decision maker's priorities. No relevant priorities should be unaccounted-for.
- **Preferentially independent:** Changes in one attribute or metric should not affect the decision maker's preferences for another attribute or metric.
- **Verifiable:** Two independent assessments yield similar results.
- **Cost-effective**: Evaluation of the metrics should be not require an intensive deployment of resources or unavailable technology.
- **Easy to communicate to a wide audience**: The public understands the scale and context of the metric and can interpret the metric with little additional explanation.
- **Changeable by human intervention**. The metric has a causal relationship between the state of the system and the variables that are under the decision-maker's control. Metrics that are independent of human action do not inform a management, policy-making, or design process.
- **Credible**: Stakeholders perceive that the metric accurately measures that which it is intended to measure.
- **Appropriate scale:** The metric is applicable at the spatial and temporal scales chosen for analysis.
- **Directed**: Metric scales whether they are qualitative or quantitative, are bi-directional polar scales,
- **Relevant**: The metric reflects stakeholder priorities and enhances the ability of managers and regulators to faithfully execute their stewardship responsibilities. There is no point assembling a metric no one cares about.
- **Sensitive:** enough to capture the minimum meaningful level of change or make the smallest distinctions that are still significant, and it would have uncertainty bounds that are easy to communicate.
- **Minimally redundant:** A smaller metric set is preferred to a larger metric set to avoid interactions or correlations with other metrics.
- **Transparent:** The metric should not be designed to serve a "hidden agenda."

It is important to acknowledge here that there will be "conflicts" among metrics, resulting in the need to make tradeoffs. For example, a tradeoff exists between achieving any significant benefit from a project and minimizing cost. The tradeoff concept is discussed in Step 5. As a consequence of such "conflicts", a given measure or alternative may not take clear precedence over other measures or alternatives in respect to every metric for evaluating performance. This may present a dilemma to decision-makers, who are trying to choose a single measure. It is important to place development of metrics prior to the development of measures because the "hard thinking" that goes into developing the metrics can create an improved set of measures; this in turn permits stakeholders to focus on thinking about the objectives rather than anchoring themselves to favored measures (Keeney and Raiffa 1976).

In the following sections and in Tables 3-1A thru 3-1E the metrics for the MsCIP are listed and described.

3.1.3.1 Environmental Quality (EQ) Metrics

Table 3-1A.
MsCIP Objectives and Metrics for Environmental Quality

Plan Performance Objectives for Risk Reduction		Metrics	(Units)	Description	Data Source
Environmental Quality	Restore and protect tidal and non-tidal habitats.	Tidal Habitat Restored	Functional units	This metric measures positive changes to the tidally-influenced wetlands that result from the implementation of a measure or plan.	Models
		Tidal Habitat Lost	Functional units	This metric measures adverse impacts to the tidally-influenced wetlands that result from the implementation of a measure or plan.	Models
		Non-tidal Habitat Restored	Functional units	This metric measures positive changes to the non-tidal ecosystem that result from the implementation of a measure or plan.	Models
		Non-tidal Habitat Lost	Functional units	This metric measures adverse impacts to the non-tidal ecosystem that result from the implementation of a measure or plan.	Models

1. Tidal Habitat Restored - This metric measures positive changes to the tidally-influenced wetlands that result from the implementation of a measure or plan. These are positive benefits from implementing a restoration plan or a combination of plans. Ecosystem components included in this metric are tidal wetlands (i.e., tidal fringes), associated threatened and endangered and other species associated with essential fish and other tidal habitats, and related losses that require mitigation due from implementation of structural plans. Units are in acres.

2. Tidal Habitat Lost - This metric measures adverse impacts to the tidally-influenced wetlands that result from the implementation of a measure or plan. Ecosystem components included in this metric are tidal wetlands (i.e., tidal fringes), associated threatened and endangered and other species associated with essential fish and other tidal habitats, and related losses that require mitigation from the implementation of structural plans. Units are in acres.

3. Non-tidal Habitat Restored - This metric measures positive changes to the non-tidal ecosystem that result from the implementation of a measure or plan. These are positive benefits from implementing a restoration plan or a combination of plans. Ecosystem components included in this metric are maritime forests, wetland pine savannah, beach and dune habitats, and associated threatened, endangered and other species in non-tidal habitats. Units for this metric are the percentage increase of quality fish and wildlife habitat in acres.

4. Non-tidal Habitat Lost- This metric measures adverse impacts to the non-tidal ecosystem that results from the implementation of a measure or plan. This has a negative impact of implementation of an array of alternatives as part of the comprehensive plan. Ecosystem components included in this metric are maritime forests, wetland pine savannah, beach and dunes, threatened, endangered and other species and their non-tidal habitats, and related losses that require mitigation due to implementation of structural plans. Units for this metric are the percentage decrease of quality fish and wildlife habitat in acres.

3.1.3.2 National Economic Development (NED) Metrics

Table 3-1B.
MsCIP Objectives and Metrics for National Economic Development

Plan Performance Objectives for Risk Reduction		Metrics	(Units)	Description	Data Source
National Economic Development	Reduce damages from catastrophic storm inundation.	Expected Annual Damages Avoided	$	The amount of storm damages reduced/avoided by a plan expressed as annualized dollars. Annualized dollars are calculated by comparing a future without a project in place versus a future with a project in place.	HEC-FDA Model
		Residual Damage	$	This metric describes what a plan does not account for (or what happens if a plan is exceeded). Residual damage is defined as the storm damage that is not prevented with the implemented plan in place (expressed as annualized dollars).	Model
		Cost of Implementation	$	The amount of money in dollars needed to implement the plan. This metric measures the cost in today's dollars to local and Federal governments to implement the recommended plan.	Empirical Data

1. Expected Annual Damages Avoided - The amount of storm damages reduced/avoided by a plan expressed as annualized dollars. Annualized dollars are calculated by comparing a future without a project in place versus a future with a project in place.

2. Residual Damage – This metric describes what a plan does not account for (or what happens if a plan is exceeded). Residual damage is defined as the storm damage that is not prevented with the implemented plan in place (expressed as annualized dollars).

3. Cost to Implement Plan – The amount of money in dollars needed to implement the plan. This metric measures the cost in today's dollars to local and Federal governments to implement the recommended plan.

3.1.3.3 Other Social Effects (OSE) Metrics

These OSE metrics focus on the preservation of people's quality of life. OSE metrics were developed addressing impacts to cultural heritage and preservation of historical structures, disruptions to public service and infrastructure and impacts to personal effects.

Table 3-1C.
MsCIP Objectives and Metrics for Other Social Effects

Plan Performance Objectives for Risk Reduction		Metrics	(Units)	Description	Data Source
Other Social Effects	Protect public health and safety from catastrophic storm inundation.	Cultural and Historical Heritage Impacts	Unitless	This metric addresses impacts to social groups, church congregations and groups with common heritages. This metric also includes impacts to aesthetics and the destruction of the human-created landscape such as historical structures.	Expert Judgment
		Public Service and Infrastructure Disruptions	Unitless	This metric includes post-flood event disruptions to schools, fire and police service, access to hospitals, libraries and community centers, and use of roads, bridges, and utilities.	Expert Judgment
		Personal Impacts	Unitless	This metric includes loss of family possessions, photographs, and impacts to people's emotional and mental health.	Expert Judgment

1. Cultural and historical heritage impacts – This metric addresses impacts to social groups, church congregations and groups with common heritages. This metric also includes impacts to aesthetics and the destruction of the human-created landscape such as historical structures. Units are a unitless quantitative scale where a score of 10 is best, 1 is worst. (i.e., 10 is least impacts to structures, 1 is most impacts).

2. Public service and infrastructure disruptions – This metric includes post-flood event disruptions to schools, fire and police service, access to hospitals, libraries and community centers, and use of roads, bridges, and utilities. Units are a unitless quantitative scale where a score of 10 is best, 1 is worst (i.e., 10 is least disruption, 1 is most disruption).

3. Personal impacts – This metric includes loss of family possessions, photographs, and impacts to people's emotional and mental health. Units are a unitless quantitative scale where a score of 10 is best, 1 is worst. (i.e., 10 is least impacts to people, 1 is most impacts).

3.1.3.4 Regional Economic Development (RED) Metrics

The RED metrics measure both positive and negative impacts to the regional economy. Positive impacts are captured by impacts to sales volume, personal income and employment and negative impacts by local cost burdens. Sales volume, income and employment will be sub-metrics under RED, and will be equally weighted. This metric is termed Positive regional economic benefits and will combine these 3 sub-metrics. The local cost burdens metric is also a sub-metric under RED and will receive a weight equal to combined weighting of the positive metrics under regional economic benefits.

Table 3-1D.
MsCIP Objectives and Metrics Regional Economic Development

Plan Performance Objectives for Risk Reduction		Metrics	(Units)	Description	Data Source
Regional Economic Development	Reduce damages from catastrophic storm inundation.	Local Cost Burden	Unitless	This metric assesses the costs that will be born locally. This includes the local cost-share with the Federal government to implement the alternative and local costs for ongoing operations and maintenance (O&M) related to the alternative. It also accounts economic impacts on the gross sales volume, personal income, and number of individuals employed in the workforce. These measures are incorporated into unitless scale.	Model/Expert Judgment
		Positive Regional Economic Benefits	Unitless	Economic benefits to the region with regards to sales volume, income and employment. This metric assesses the potential impacts of sales volume change and personal income in dollars and regional employment change in number of jobs to the local economy.	Expert Judgment

1. Local Cost Burdens – This metric represents costs born locally. This includes cost-sharing with the Federal government to implement the recommended plan and local costs for ongoing operations and maintenance (O&M) related to the implemented plan. The local cost burdens may include costs associated with maintenance workers needed to maintain infrastructure of the recommended plan. Units are a unitless quantitative scale where a score of 10 is best, 1 is worst.

2. Positive regional economic benefits – Economic benefits to the region with regards to sales volume, income and employment. This metric assesses the potential impacts of sales volume change and personal income in dollars and regional employment change in number of jobs to the local economy. Units are a unitless quantitative scale where a score of 10 is best, 1 is worst.

3.1.3.5 Comprehensive Risk Metrics

The following risk metrics serve as additional information to decision makers. They are a way to address extreme cases of uncertainty.

Table 3-1E.
MsCIP Objectives and Metrics for Comprehensive Risk

Plan Performance Objectives for Risk Reduction		Metrics	(Units)	Description	Data Source
Comprehensive Risk	Reduce plan risk.	Long-term Sustainability of Plan	Unitless	The risk that features associated with the recommended plan will not perform as intended (over time) due to factors such as cost, human behavior, technical level of maintenance required, political concerns, resource availability, local funding per year, and operational reliability.	Expert Judgment
		Residual Risk	Unitless	This metric describes what a plan does not account for (or what happens if a plan is exceeded). Residual risk is defined as the storm damage risk that remains with the implemented plan in place (expressed as annualized dollars).	Empirical Data/Expert Judgment
		Consequences of Plan Failing	Unitless	This metric describes what happens if a plan does not work as intended. It describes consequences to humans and the environment due to a catastrophic failure of an implemented plan under design conditions or other sets of circumstances from a storm event.	Expert Judgment

1. Long-term Sustainability of Plan – The risk that features associated with the recommended plan will not perform as intended (over time) due to factors such as cost, human behavior, technical level of maintenance required, political concerns, resource availability, local funding per year, and operational reliability. Units are a unitless quantitative scale where a score of 10 is best, 1 is worst (i.e., 10 is least risk, 1 is most risk).

2. Residual Risk – This metric describes what a plan does not account for (or what happens if a plan is exceeded). Residual risk is defined as the storm damage risk that remains with the implemented plan in place (expressed as annualized dollars). It accounts for the following factors: erosion, wildlife species, wildlife habitat, salt water intrusion, surge damages, drainage, wind, maximum probable intensity (MPI) plan (accounts for more intense storm), cultural heritage, and infrastructure. Units are a unitless quantitative scale where a score of 10 is best, 1 is worst.

3. Consequences of Plan Failing – This metric describes what happens if a plan does not work as intended. In other words, it describes consequences to humans and the environment due to a catastrophic failure of an implemented plan under design conditions or other sets of circumstances from a storm event. The greatest risk is risk of failure to structural measures, such as levees, flood gates, etc. Consequences and likelihood of failure vary depending on the line of defense. For example, risk of Line 2 failure is more likely, but consequences are relatively low; risk of Line 4 failure is highly unlikely, but consequences are very high. It includes the following factors: injuries to population, loss of infrastructure, loss of habitat, and loss of wildlife species. Units are a unitless quantitative scale where a score of 10 is best, 1 is worst.

3.2. Step 2: Inventory and Forecast to Establish Baseline Conditions

In this step of the planning process, models and tools are selected to simulate decision outcomes in terms of the selected performance metrics. There is often uncertainty in projecting decision outcomes and, when planning horizons are long, a considerable amount of uncertainty may be unavoidable. Nominal forecasts of decision outcomes, those forecasts made assuming baseline conditions or "business as usual" conditions, should therefore be qualified by considering what implications uncertainty in these assumptions may have for the decision recommendations. Uncertainty is a lack of knowledge that originates from an incomplete understanding of the structure and function of natural or manmade systems (*e.g.*, coastal hydraulics at the mouth of the Mississippi).[1] Uncertainty is often classified as either model uncertainty or parameter uncertainty. Model uncertainty is a lack of knowledge about the proper structure of a model (*e.g.*, choice of a two vs. a three dimensional model to simulate hydrodynamics). Parameter uncertainty is the lack of knowledge about the best value to use as an input parameter value for the chosen model.

One of the advantages of decision analysis is its ability to assist decision makers to make rational decisions in the face of uncertainty. A full uncertainty analysis of the decision would culminate in a probability distribution over the utility of decision outcomes. However, considerable effort may be needed to reach such a conclusion. Often, a sensitivity analysis that considers how the decision recommendations might change under different assumptions may be adequate. Neither sensitivity nor uncertainty analysis of this decision were undertaken for MsCIP at this point.

1 Although the mathematics used to describe variability and uncertainty is essentially similar, uncertainty is widely recognized as being distinct from natural variability. Variability describes the heterogeneity in an inherently random value. For example, the heterogeneity of some size attribute within a population. This variability is, in principle, not reducible (Morgan and Henrion 1990). In contrast, uncertainty can be thought of as a lack of knowledge about what parameter value to use in a model or how to represent a process in a mechanistic model. This lack of knowledge might in principle be reduced, although reducing some uncertainties can often be difficult in practice.

3.3 Step 3: Formulate alternative plans

3.3.1 Plan Formulation

Plan formulation is the process of building plans that meet planning objectives and avoid planning constraints. It requires the knowledge, experience, and judgments from many professional disciplines, as well as the views of stakeholders, other agencies and non-governmental organizations (NGOs), and the public. Plan formulation capitalizes on imagination and creativity wherever it is found, across technical backgrounds and group affiliations. Formulating plans includes developing management measures (e.g., structural and non-structural), identifying planning units, conducting screening of measures, and combining measures into alternative plans. Plans include abilities to be modified into the future within the adaptive management framework. For more details on the formulation of plans and planning units for MsCIP, refer to the Main Report.

3.4 Step 4: Evaluate effects of alternative plans

Once the plans have been formulated, the performance of each plan with respect to each metric is estimated for each decision alternative and scenario. The SAM Technical Team accomplished this step using mechanistic or empirical models of physical, economic, and social systems where available and expert judgment where such models were not available. Sources of metric data are presented in Tables 3-1A thru 3-1E.

3.5 Step 5: Compare alternative plans

In this step, the objective is to rank the decision alternatives (plans) using an abstract utility measure that integrates information about anticipated performance outcomes and stakeholder interests. The MCDA approach used for MsCIP is multi-attribute utility theory (MAUT) (Keeney and Raiffa 1976). With respect to its applications in MCDA, the advantage of MAUT is that it converts a multi-objective decision with competing objectives to a single objective problem for which the objective is to maximize utility given information about the decision maker's preferences. The purpose of this section is to provide an overview of the approach. Sub-section 3.5.1 describes how information on stakeholder preferences is brought into the decision making process. Sub-section 3.5.2 describes the calculation of a multi-attribute utility score, the ranking of decision alternatives, and decision analysis. Sub-section 3.5.3 describes how sensitivity and uncertainty analysis can be used in conjunction with MCDA specifically to support risk-informed decision making. Specific details about this application of RIDF are provided in Section 4.0.

3.5.1 Stakeholder Preferences

The first step toward developing a multi-attribute utility function is to collect information on stakeholder preferences by finding out how much importance stakeholders place on the various decision objectives. Information about stakeholder preferences is obtained through workshops during which stakeholders participate in a series of assessments designed to obtain information on their preferences. These preferences are expressed as relative weights on decision objectives. These weights are subsequently incorporated into a multi-attribute utility function that is then used to

calculate the utility score by which decision alternatives are ranked. This process gives stakeholders an active role in the decision making process because, if stakeholder weights are used in the utility function, the ranking of plans is then tied directly to their preferences.

Since stakeholders can exhibit a diverse set of preference patterns, it is important to consider how this diversity of preference will be treated in the decision analysis. If there are many stakeholders, their sheer number may make it very difficult to consider each ones preferences individually. In addition, there would be much redundancy in such an approach because most stakeholders appear to have some recognizable preference patterns. On the other hand, aggregating stakeholders into a single group and averaging their weights to represent an amalgamated public interest is also not a good strategy, particularly if diverse values have been expressed in the stakeholder population. An averaged set of weights would tend to converge on an equal distribution of weights across the decision objectives and/or a set of weights that is not likely to represent anybody's interests in particular.

The approach used in this analysis is to analyze the sets of weights obtained from individual stakeholders and then classify them based on their expressions of common preference patterns. For classification purposes, we rely on a set of multivariate statistical techniques known as cluster analysis to identify distinct preference patterns that exist within the stakeholder population. Once stakeholders have been segregated based on their preferences, the patterns of preference that are characteristic of each group can be represented by averaging their weights on decision objectives. At this time, no particular consideration is given to the prevalence of each preference pattern in the MsCIP project area. The primary concern is to understand what patterns of preference exist in the project area and what affect these different patterns of preference might have on the choice of a risk-reduction plan.

3.5.2 Multi-attribute Utility and MCDA

The multi-attribute utility function transforms the metrics for the several objectives to a single, aggregate measure of utility. The utility function is compensatory in the sense that it allows progress on one objective to substitute for lack of progress on another objective. The rate of compensation depends upon the relative weight on each objective, which depends upon the preferences of the decision maker. Multi-attribute utility (*U*) is the weighted sum of *L* outcome measures of performance,

$$V(m_{jkl}) : U_{jk} = \sum_{l} w_l V(m_{jkl}) .$$

Outcome measures of performance are evaluated through modeling studies for

$$j = \{1,2,3,..., J\}$$

decision alternatives and

$$k = \{1,2,3,..., K\}$$

planning scenarios. Planning scenarios represent the range of possible futures under which plan performance may be realized. A set of weights (*w*) that reflects the relative importance of each decision objective is elicited from the decision maker and/or stakeholders using a direct weighting

procedure (see Section 3.5.1). Weights may take any value between zero and one, but must sum exactly to one. Value scores are then calculated from a linear utility function for each metric,

$$V(m_{jkl}),$$

that is either increasing or decreasing with that metric, m_{jkl}. For an economic "good" (*i.e.*, more is better):

$$V(m_{jkl}) = \frac{m_{jkl} - \underset{jk}{MIN}(m_{jkl})}{\underset{jk}{MAX}(m_{jkl}) - \underset{jk}{MIN}(m_{jkl})}$$

and for an economic "bad":

$$V(m_{jkl}) = 1 - \frac{m_{jkl} - \underset{jk}{MIN}(m_{jkl})}{\underset{jk}{MAX}(m_{jkl}) - \underset{jk}{MIN}(m_{jkl})},$$

where the *MIN* and *MAX* functions are over all decision alternatives and scenarios. Each scenario is represented by a set of possible values for uncertain variables in hydrologic and economic models used to simulate outcome measures of performance. Value and utility scores, which are bounded by 0 and 1 so that scores closer to 0 indicate less desirable outcomes, are calculated for the outcome of each alternative and scenario, including a "No Action" alternative.

In MCDA without uncertainty, the objective is to maximize the multi-attribute utility function for a set of stakeholder preferences by choosing the "best" decision alternative. Results of the analysis can also be presented more comprehensively by ranking the alternatives by their utility score. This is useful because much can be learned about the alternatives themselves by observing how the utility score varies from one alternative to another. For example, it is possible that some alternatives may yield as much utility as the preferred alternative, but do so because they accentuate performance on a different set of objectives. Just as results of a decision analysis are conditioned on the assumptions used to simulate performance outcomes, the results of the decision analysis and plan rankings also depend in part upon what set of stakeholder weights are used in the multi-attribute utility function. Thus, it is also useful to examine the sensitivity of plan rankings to the weights on decision objectives. If plan rankings are not sensitive to the weights, this may suggest that the alternative may have a broad base of support among stakeholders.

3.6 Step 6: Select recommended plan

Analysis of the project selection decision using the risk-informed decision process should provide a basis for recommending a risk-reduction plan for each planning unit. This recommendation will be based on all of the information assembled during the planning process including information on stakeholder preferences, performance outcomes, and both risk and uncertainty. An advantage of the RIDF is that the process of plan selection is a transparent and rational one. Decision makers should be able to rely on the results of RIDF analysis as long as all of the factors, issues, and concerns of relevance have been accounted for among the decision objectives. Care should be taken to minimize the number of factors germane to a decision that remain outside the formal

scoring and ranking process. In other words, the decision model implemented using MAUT should include as many of the concerns, objectives, and factors that are relevant to decision-making as possible. Given the large number of parties relevant to the decisions under consideration (The Corps, other Federal agencies, Congress, state, counties, cities, stakeholders, the public), great care must be taken to ensure that the planning process is comprehensive in its approach to the interests and values of these parties.

4. APPLICATION OF RIDF TO MSCIP PROJECT SELECTION

4.1 Stakeholder Workshops Activities Summary

The purpose of the weight elicitation workshop held on 10-11 September 2007 was to develop a transparent process to provide decision makers with key stakeholder group perspectives (traditional process used mainly NED and RED criteria to select a plan). We wanted to capture stakeholder value information that guides the ranking of plans and recommendations. We also wanted to document differences among stakeholders so that we can identify consensus areas and potential compromises. This makes it easier to find common ground in selecting a plan. We documented these differences by comparing the performance of different plans by looking at different metrics for each plan. A common set of metrics was used to facilitate negotiation. Stakeholders were actively engaged in weighting the metrics during the workshop.

The workshop involved using questionnaires (survey instruments) to elicit weights of individuals from key stakeholder groups. The objective of the workshop was to conduct sessions with key stakeholders where their weights were elicited and their weight judgments summarized. Both the direct score and swing weight methods were used to elicit these weights. The workshop was held in Biloxi, MS at the Mississippi Department of Marine Resources building, Room 205.

Stakeholder groups were selected for participation in this effort based on their participation in previous MsCIP stakeholder meetings. These groups and individuals were selected by the MsCIP team in advance to ensure diversity of opinions. Key stakeholder groups included individuals from government (Federal, state, and local), non-governmental organizations (NGOs), and individuals representing various environmental, business, development, and academic institutions. The Corps (MsCIP technical team and the ERDC) also submitted weights.

To kick off the stakeholder session, the MsCIP technical team and ERDC described the background and purpose of the workshop and answered questions or concerns that arose. We discussed the metric set, its importance and clarified metric definitions as appropriate. We also described through specific hypothetical examples the swing weight process and how stakeholder weights will be generated using this method. Draft data for the set of 15 metrics were included in the matrix. Weights were obtained for the final set of 15 metrics (see Tables 4-1). We elicited and received input from each of the stakeholder groups on the metric set and its completeness.

A series of “polls” were conducted. In the first of these, participants were asked to provide an ordinal ranking of the 15 individual metrics from most to least important, where each participant was asked

to “wear the hat” of their job within their organization. The results were shared and discussed briefly. Next, the stakeholders were asked to allocate points to each metric, thus providing finer distinction of the relative importance of metrics. Allocation was done with three rules. First, no individual metric could be given more than 70 points. Second, 100 points was available for the sum total of points given to all metrics. Third, all 100 points must be used. The same process was used of first ranking and then allocating points to the “categorical” metrics (NED, RED, OSE, and EQ). Thus, each of the stakeholder sessions progressed according to the following weight elicitation activities:

- Round 1: ranks were obtained for the list of 15 metrics.
- Round 2: rate (allocate) 15 metrics using 0-100 scale.
- Round 3: rank 15 metrics from 1-15.
- Round 4: rate (allocate) these metrics using 0-100 scale.

An intranet-based system was used to gather weight data from participants. Each participant accessed a dedicated PC to rank metrics. These results were compiled real-time and shared with the group so that weights could be discussed.

The RIDF and SAM Technical Team members attended to answer technical questions that arose and to document the process. Group Solutions, a Corps contractor, facilitated each session and electronically elicited the weights from each of the stakeholder groups. Group Solutions compiled the resultant weights and submitted all results electronically to ERDC for analysis and reporting.

Following the workshops, input values for metrics were combined with information about values and weighting functions for the various metrics to generate an overall score for each plan being considered. These scores will allow for direct comparisons to be made across all measures/plans and to rank plans in relation to each other in terms of the degree to which they satisfy the objectives the MsCIP metrics represent. Such scores can be used to evaluate measures or plans against the without project condition, as well as to compare the performance of individual measures or plans (see more detailed discussion below).

Session Participants and Organizations

Tables A1-1 to A1-6 in Annex 1 list in alphabetical order the people (and corresponding affiliation) who participated in the MsCIP stakeholder sessions. Some of those listed in the tables collaborated while others started but did not complete the weighting process.

4.2 Stakeholder Weightings

The MsCIP weight elicitation sessions yielded 45 complete sets of weights on fifteen metrics. We used a cluster analysis, an exploratory data reduction technique, to classify stakeholders with similar preference patterns expressed through their allocation of weights to metrics. These results enable us to identify and characterize patterns of preferences that exist in the project area.

Several different clustering techniques are available and applications of these methods would lead to alternative cluster solutions. The standard for evaluating solutions is whether or not the resulting solutions can be explained and are meaningful in the context of their purpose. In this case, the

objective of the analysis is to identify and document the existence of distinct patterns of preferences within the subject population and characterize preference patterns. Characteristic preference patterns are then used to analyze the sensitivity of the decision to stakeholder preferences. This enables the sensitivity analysis to focus only on those preference patterns that have been observed, while excluding from the analysis those that have not been observed. The data reduction also eliminates the duplication of effort associated with carrying out sensitivity analysis for preference patterns that are essentially similar.

A number of clustering techniques were tested to evaluate the sensitivity of clusters to the choice of clustering method. The selected method employs a hierarchical agglomerative clustering technique called Ward's minimum variance method. In this method, an initial cluster of two individuals is formed by considering all possible clusters of size two and combining those individuals that produce the least impairment in an objective function. In the subsequent stage, all possible combinations of two individuals and all possible combinations of three individuals that include the initial cluster are formed and the cluster that results in least impairment of the objective function is accepted. At each level of the hierarchy, the objective function is minimized over all partitions of the data (Dillon and Goldstein 1984, SAS 2004). Although slightly different methods might produce clusters consisting of somewhat different individuals, we found that different methods identified a set of clusters that differed in similar ways.

Clusters were tested using two versions of the weight data. We used the raw weights that were allocated through direct weight elicitation to the fifteen metrics and we also used an aggregate weight statistic in which the fifteen metrics were aggregated into four metrics that correspond to the USACE system of accounts. Aggregate weights by planning objective are the sum of weights allocated to individual metrics associated with National Economic Objectives (NED), Regional Economic Objectives (RED), Environmental Objectives (EQ), and Other Social Effects (OSE). When the weights are aggregated this way, the data have fewer dimensions and the clusters are more clearly delineated. For this analysis, the comprehensive risk metrics that were identified in Section 3.1.3.5 were subsumed into one of the system of accounts. Long-term sustainability (Metric 13) and consequences of plan failing (Metric 14) are subsumed into the RED account. Residual risk (Metric 15) was subsumed into the NED account.

4.2.1 Analysis of Stakeholder Weights

The MsCIP weight elicitation sessions yielded 45 complete sets of stakeholder weights on the set of fifteen metrics (Annex 2). Four clusters emerged from the weight elicitation results. Mean weights are summarized in Table 4-1 for each metric and in Table 4-2 for each aggregation of weights by planning objective. The smallest cluster, D, contains six individuals and the largest cluster, B, contains 15 individuals. The formation of each cluster explains at least five percent of the variation in respondent's allocation of weights to the aggregate planning objectives. Five respondents were classified as outliers and therefore are not included in any particular cluster. Figure 4-1 shows the mean weight for each aggregate planning objective and each cluster. This graph can be used to help develop explanations for why the different clusters emerged. For example, group A places the highest weight on RED and Group D places the highest weight on EQ.

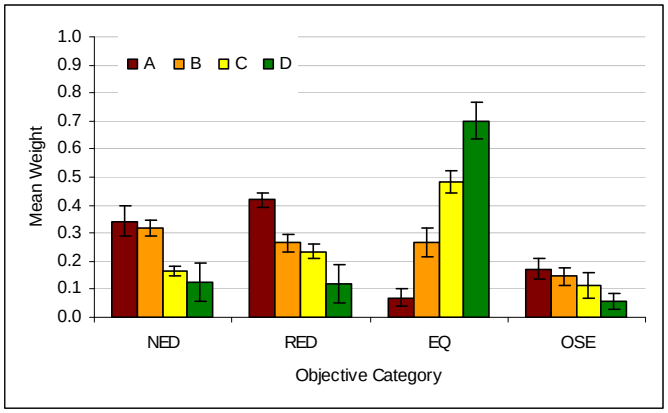
Table 4-1.
Mean Weight for each Metric by Cluster

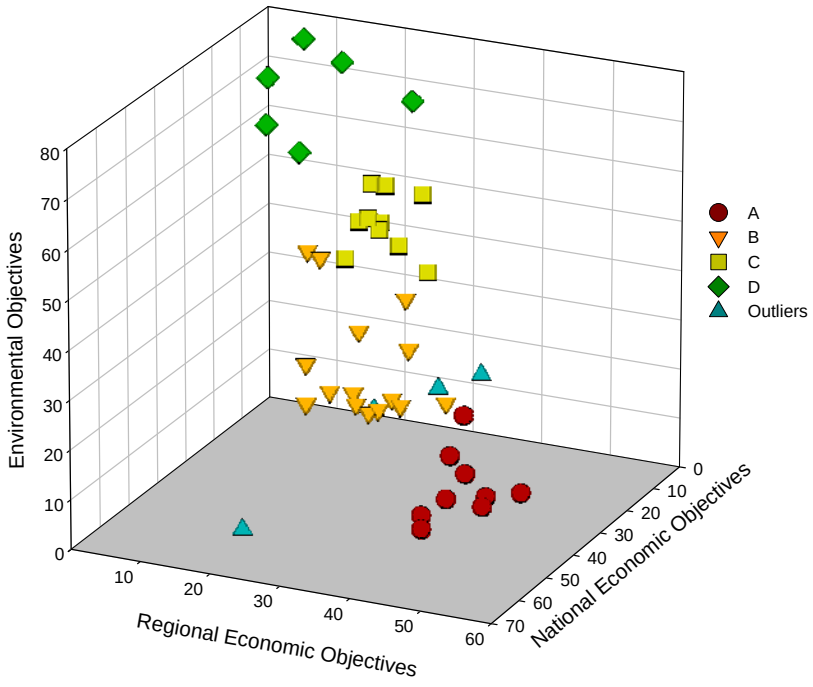
Metric Description			Cluster			
		Category	A	B	C	D
1	Tidal Habitat Restored	EQ	0.02	0.07	0.12	0.21
2	Tidal Habitat Lost	EQ	0.02	0.09	0.17	0.18
3	Non-Tidal Habitat Restored	EQ	0.02	0.05	0.09	0.13
4	Non Tidal Habitat Lost	EQ	0.02	0.06	0.12	0.18
5	Damage Reduced/Avoided	NED	0.14	0.11	0.05	0.04
6	Residual Damages	NED	0.06	0.07	0.03	0.04
7	Cost to Implement Plan	NED	0.10	0.09	0.06	0.02
8	Local Cost Burden	RED	0.12	0.07	0.05	0.02
9	Regional Economic Benefits	RED	0.08	0.06	0.03	0.02
10	Cultural and Historical Heritage	OSE	0.05	0.04	0.05	0.02
11	Public Service Disruptions	OSE	0.08	0.06	0.04	0.02
12	Personal Impacts	OSE	0.05	0.05	0.03	0.02
13	Long-Term Sustainability	RED	0.13	0.08	0.09	0.05
14	Consequences of Plan Failure	RED	0.08	0.07	0.06	0.03
15	Residual Risk	NED	0.04	0.06	0.02	0.03

Table 4-2.
Mean Weight for each Aggregate Planning Objective by Cluster

Cluster	Respondents (Number)	Aggregate Planning Objective			
		NED	RED	EQ	OSE
A	9	0.34	0.42	0.07	0.17
B	15	0.32	0.27	0.27	0.15
C	10	0.17	0.24	0.48	0.12
D	6	0.12	0.12	0.70	0.06

(5 respondents are outliers)





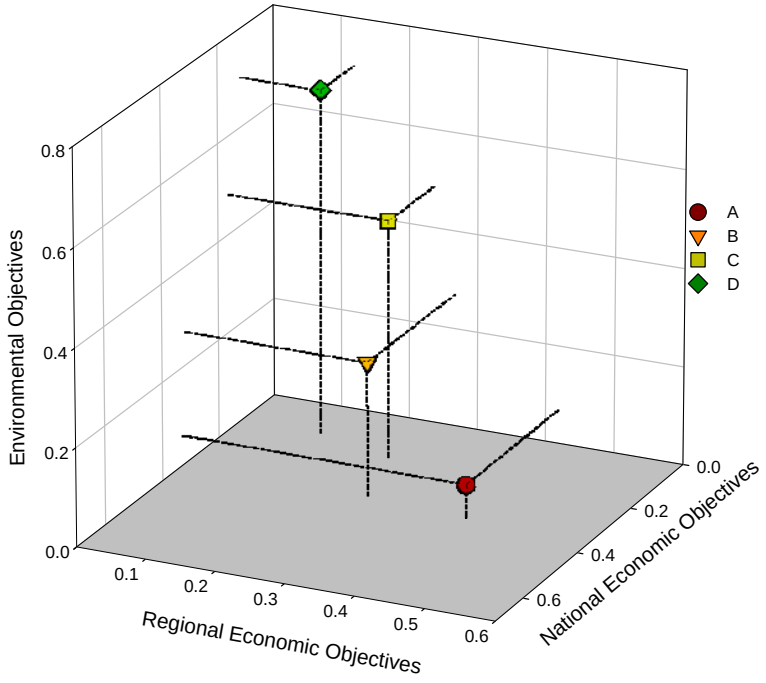


Figure 4-1. Mean weights by aggregate planning objective for four clusters, A through D. Uncertainty bounds represent 95% confidence limits on the estimated mean weight.

Differences among the clusters are further illustrated in Figures 4-2(a) and 4-2(b) which show the individual respondent weights arrayed in three-dimensional space. These results are not displayed in the OSE dimension because of relatively small differences in that dimension.

Performing the cluster analysis in this manner identifies distinct stakeholder group preferences across the Mississippi coast. These four groups represent differing stakeholder values and each will be used to rank alternative plans. This will permit us to document differences among stakeholders and identify areas for consensus and potential compromise. This information guides the ranking of plans and recommendations, as described below.

(a)

(b)

Figure 4-2: Weight allocation arrayed in three dimensions showing four clusters (a) and mean weight allocation for each cluster (b)

4.2.2 Cluster Groups

The cluster analysis identified four (4) distinct groups (or clusters) of stakeholders using stakeholder's allocation of weights across the fifteen metrics. Each group is described below relative to each of the four system of accounts, or objective categories on a 0-1 scale (see Table 4-2 and Figure 4-1).

- Cluster A: This group's focus was on economic development at both the regional and national levels. It had the highest NED weighting of 0.42 and the highest RED weighting of 0.34. This group also had the highest OSE weight (0.17) and the lowest weight for EQ (0.07).
- Cluster B: This group was intermediate (not highest or lowest weight for any category), allocating at least a weight of 0.15 to each category. It was unique in that it provided the second-highest weights for three categories: NED (0.32), RED (0.27) and OSE (0.15).
- Cluster C: While this group focused on EQ, giving it the second-highest weight (0.48), this group also weighted (balanced) each of the other categories with at least a 0.12 weighting, which sets it apart from Cluster D.
- Cluster D: This group is the most focused on the EQ category, showing the highest EQ weight of 0.70. This high EQ weighting comes at the expense of the other 3 categories, yielding the lowest weights for RED (0.12), NED (0.12) and OSE (0.06).

4.3 Plan Rankings by Multi-attribute Utility (MAU) Score

In this analysis, an MAU score is calculated and plans are ranked by the MAU score. Plans with higher MAU scores are preferred, but these ranks assume a particular set of stakeholder preferences and planning assumptions.

4.3.1 Ranking of Measures

MAU scores were calculated for each of the measures and the no-action alternative using a full set of fifteen weights and metrics. The alternatives are then ranked by MAU score, with the alternative having the highest MAU score being most preferred given the preferences under consideration. However, these ranks should be interpreted with more caution than this because there are many uncertainties that have not been fully addressed in this analysis. Therefore, rather than focusing on identifying the top-ranked plan and choosing this as the "best" alternative, it may be more useful to consider other types of questions. For example:

- How much do the MAU scores vary across the alternatives?
- Is there a group of plans at the top that have MAU scores that are relatively close to one another? What are the similarities and differences of the plans that form this "top tier?"
- How sensitive are plan rankings to planning assumptions and stakeholder preferences?
- Do stakeholders with different preference patterns prefer one particular plan but for different reasons?

Results of the analysis are presented in the form of numerous tables and graphs that summarize the results for each planning unit so that they can be used to support these types of deliberations among decision makers and stakeholders.

4.3.2 Summary of Results

Results of the MCDA are summarized in Table 4-3 for each cluster group of preference pattern. An independent MCDA was completed in each of the nine subdivisions. Stakeholder preferences are assumed to be consistent across subdivisions and the preferred plan in one subdivision is assumed to be independent of choices in every other subdivision or project alternatives (see Chapter 5 of Main Report for discussion of alternatives). Therefore, when aggregated, the combination of preferred plans in Table 4-3 represents a comprehensive suite of projects for each preference pattern. For example, stakeholders with preferences consistent with those of preference pattern A are best-served by a plan that consists of a suite of projects including the Barrier Islands Comprehensive Plan, Option K in LOD2, Bayou Cumbest Acquisition, Forrest Heights Plan 2, the High-risk Homeowner's plan. These stakeholders prefer no action in Turkey Creek, Admiral Island, Dantzler, and Franklin Creek subdivisions. Although Table 4-3 suggests that, in some cases, some stakeholders would prefer the no action alternative in some subdivisions, each subdivision has at least one preference pattern for which an action plan is preferred by at least one preference pattern.

Table 4-3.
Summary of Decision Analysis Results by Preference Pattern and Subdivision

Subdivision	Preference Pattern			
	A	**B**	**C**	**D**
Barrier Islands	Comprehensive Plan	Comprehensive Plan	Option A	Option A
LOD2	Option K	Option K	Option K	Option K
Turkey Creek	No Action	No Action	No Action	Ecosystem Plan 1
Bayou Cumbest	Acquisition	Acquisition	Acquisition	Ecosystem Plan 1
Admiral Island	No Action	No Action	No Action	Ecosystem Plan 1
Dantzler	No Action	No Action	No Action	Ecosystem Plan 1
Franklin Creek	No Action	No Action	No Action	Ecosystem Plan 1
Forrest Heights	Plan 2	Plan 2	No Action	No Action
Non-Structural	High Risk HARP	Long-term HARP	High Risk HARP	Long-term HARP

HARP = Homeowner's Relocation and Assistance Plan

The calculation of the MAU score is summarized for each of the four preference patterns in Annex 3. In most subdivisions, at least one of the fifteen metrics did not vary across the decision alternatives. If a metric did not vary, it was dropped from the calculation of MAU and the weights for all preference patterns in that subdivision were re-scaled to sum to one. The consequence of this re-scaling is that MAU scores cannot be compared across subdivisions. For example, the Barrier Island Comprehensive Plan has an MAU score of 0.7393 for preference pattern A. This score should not be compared to an MAU score in Dantzler or any other subdivision. There are fifteen outcome metrics of performance associated with each decision outcome. If none of the decision alternatives being considered in a subdivision would have any impact on an outcome measure of performance, that outcome measure is irrelevant to the decision because it cannot affect the choice. Moreover, if the maximum value of an outcome metric for a set of alternatives is the same as the maximum value of that outcome metric (the case of non-varying metrics), it is impossible to calculate a value score

using the equations on lines 6 and 8 on page 41 and a multi-attribute utility score cannot be calculated. Therefore, non-varying metrics are dropped. Dropping these metrics will have no effect on the decision (*i.e.,* which alternative is chosen) because there is a linear utility function.

Figures 4-3 through 4-11 illustrate project rankings and show the relative contribution of each metric to the overall multi-attribute utility (MAU) score. This is illustrated by the color banding of the vertical bar in each figure. A larger color band for a metric indicates that metric contributes more to multi-attribute utility than metrics with smaller bands. One of the results of this study is that in some subdivisions, stakeholders with different preference patterns may prefer similar measures for different reasons. For example, in Figure 4-4, LOD2 Option K is associated with the highest MAU for all preference patterns. It is sometimes the case that stakeholders with different preference patterns prefer the same plan, but they prefer the plan for different reasons. In these cases, MCDA can serve as a way to recognize these situations, help focus the debate and discussion on only the issues that matter, and promote consensus within a diverse group.

In the Barrier Islands (Figure 4-3), the Comprehensive Plan and Plan A are preferred by all preference patterns, but their ordering depends upon preferences. In LOD2 (Figure 4-4), Option K is preferred by all preference patterns. In Turkey Creek (Figure 4-5), the No Action plan is preferred by preference patterns A, B, and C. Preference pattern D prefers Plan 1. In Bayou Cumbest (Figure 4-6), Acquisition is the preferred alternative for preference patterns A, B, and C with the No Action plan coming in ahead of the other plans for preference patterns A and C. For preference pattern B, the No Action plan is least preferred. For preference pattern D, the preferred plan in Bayou Cumbest is Plan 1. For Admiral Island (Figure 4-7), Dantzler (Figure 4-8), and Franklin Creek (Figure 4-9), the No Action plan is preferred for preference patterns A, B, and C. Plan 1 is preferred for preference pattern D. In Forrest Heights (Figure 4-10), Plan 2 is preferred by preference patterns A and B. The No Action plan is preferred by preference patterns C and D. Among the Non-structural program alternatives (Figure 4-11), the High-risk Homeowner's Plan is preferred by preference patterns A and C and Long-term Homeowner's Plan is preferred by preference pattern B and D.

5. DISCUSSION

This application of RIDF has focused on developing an objectives hierarchy for MsCIP measures selection, identifying a set of metrics to model performance outcomes, and developing a multi-attribute utility function to rate the relative performance of project alternatives. In the analysis of results, MsCIP measures alternatives are ranked by MAU score using four different sets of attribute weights. Each set of weights characterizes a pattern of preference that is represented by a group of individuals, or cluster, within the stakeholder community. Plans are ranked by MAU score and, in the absence of uncertainty in the assumptions used to model plan outcomes, the preferred measure for each cluster is the measure with the highest MAU score. However, most decisions with long-range planning horizons involve a considerable amount of uncertainty and MsCIP is no exception.

In addition to enhancing the Corps' six-step P&G guidelines by providing a means to consider multiple objectives in the decision process, RIDF also offers a mechanism by which to engage stakeholders more actively in the Corps' planning process. For example, these MCDA procedures help decision makers and stakeholders: 1) systematically structure the decision process; 2) assess tradeoffs among decision objectives; 3) reflect upon, articulate, and apply explicit value judgments concerning conflicting decision criteria; 4) make more consistent and rational evaluations of risks and uncertainties; and 5) facilitate negotiation (Hobbs and Meier 2000). In addition to improving the quality of decisions, RIDF helps decision makers engage stakeholders. Stakeholders assist decision makers to develop an objectives hierarchy and to assess the relative importance of those decision objectives. An obvious benefit of engaging stakeholders during the planning process is that this is likely to engender greater trust and confidence on the part of stakeholders and may enhance the sense of legitimacy of the decision or final outcome. The objectives hierarchy is described in Section 3.1.3 and the stakeholder weight elicitation sessions are described in Section 4.1.

Results of the stakeholder weight elicitation sessions are analyzed using cluster analysis to identify characteristic patterns of preference in the stakeholder population. The rationale for this method is that it provides an objective approach to classifying stakeholders based on psychometric data obtained directly from them. Four characteristic patterns of preference emerged from the results of weight elicitation. These preference patterns can be differentiated by the aggregate weight on EQ objectives, which is the sum of relative weights on individual EQ sub-objectives. The aggregate weight on EQ objectives is negatively correlated with the aggregate weight on each of the remaining higher level objectives: NED, RED, and OSE. Preference pattern A places the greatest emphasis on NED and RED objectives while preference pattern D places the greatest emphasis on EQ objectives. OSE objectives are consistently rated low relative to the other objectives, but preference pattern A gives slightly more emphasis to OSE objectives than EQ objectives.

This study describes why the outcomes associated with some alternatives are preferred by various stakeholders to others. Utility provides a relative measure with which to compare decision outcomes given a set of objectives and the preferences of a subject. The contribution of an attribute to utility is determined by the relative importance placed on a performance objective and the relative performance of the alternative with respect to that decision objective. Plan rankings will tend to be more strongly influenced by those decision attributes that have both a high weight and a large amount of variability in performance outcomes across plans. If relative performance does not vary much across the alternatives, then these metrics should have little impact on the decision. Similarly,

an objective that is unimportant (receives a low weight) should also have little impact on the decision, even if the corresponding metric varies a lot from one alternative to another. Metrics that do not vary much do not affect the plan rankings. For MsCIP, at least one metric in each subdivision was eliminated because it exhibited no variation across decision alternatives. Weights on decision objectives were scaled in each sub-division to accommodate the elimination of metrics.

Results of the MCDA are summarized in Table 4-3 and in the ensuing figures. A great deal can be learned by analyzing the MCDA for these four distinctly different patterns of preference. For the Barrier Islands Ecosystem Restoration, Option A and the Comprehensive Plan form a top tier of decision alternatives (Figure 4-3). These plans outrank the seven other plans for each preference pattern. Although preference patterns A and B prefer the Comprehensive Plan and preference patterns C and D prefer Option A, the differences in the MAU scores between these two plans appears relatively small for each preference pattern. This suggests that, while the different preference patterns express wildly different values and priorities, stakeholders could reach consensus around one of these two plans. Each preference pattern prefers the similar decision alternatives, but for different reasons. A similar result is observed in the LOD2 subdivision, where Option K is preferred to other alternatives for all preference patterns (Figure 4-4).

Results in other subdivisions are slightly more complicated. In Turkey Creek (Figure 4-5), Admiral Island (Figure 4-7), Dantzler (Figure 4-8), and Franklin Creek (Figure 4-9), preference patterns A, B, and C all prefer the No Action alternative while preference pattern D, which has a high weight on environmental objectives, prefers Ecosystem Plan 1. A similar pattern is observed in Bayou Cumbest (Figure 4-6) where preference patterns A, B, and C all prefer Acquisition while preference pattern D prefers Ecosystem Plan 1. It is worth pointing out that, in each case, the MAU score for the preferred alternative stands out as apparently higher than the MAU score for the other alternatives. In Forrest Heights (Figure 4-10), Plan 2 has the highest MAU score for preference patterns A and B while the No Action alternative ranks highest for preference patterns C and D. Among the Non-structural alternatives (Figure 4-11), the High Risk Homeowners Assistance Plan has the highest MAU score for preference patterns A and C while the Long-term Homeowners Assistance Plan has the highest MAU score for preference patterns B and D.

One of the benefits of subjecting policy decisions such as those being considered in MsCIP to a multi-attribute decision analysis and stakeholder involvement is that it helps decision makers to identify where common interests exist. It is possible to analyze the results to identify where and how bridges might be built to unite stakeholders who hold competing views, and where more work may be needed to evaluate decision alternatives. The results of this analysis suggest that, given the information that is available at this time, stakeholder consensus is a real possibility in the Barrier Islands and LOD2 subdivisions. For Turkey Creek, Bayou Cumbest, Admiral Island, Dantzler, and Franklin Creek, there is a modal preference for the No Action alternative among the preference patterns considered in this report. More work may be needed differentiate among the alternatives will be needed to develop recommendations for the Forrest Heights and Non-structural subdivisions.

Although a plan may have a high rank over a large number of preference patterns, the utility of that plan for one or more of those preference types may be substantially lower than for others. In this case, consideration should be given to how large these differences in utility are, whether or not these differences represent an inequity, and to what extent this outcome may be the product of having considered only a limited scope of decision alternatives.

6. LESSONS LEARNED FROM IMPLEMENTATION OF THE RIDF

Stakeholder input is being used by US Army Corps of Engineers to inform itself about the interests and values of the stakeholders who will be affected by the planning process. However, the ultimate responsibility for this project selection decision rests solely with the US Army Corps of Engineers. The agency is legally bound to act only within the mission and authority that it was given by Congress.

A number of lessons were learned in this application of RIDF that suggest recommendations for future planning studies that use this method. For example, it is important that sufficient attention be given to developing the objectives hierarchy and selecting the metrics. The time spent structuring an objectives hierarchy will assist in helping the decision maker to clarify his objectives and the use of poorly structured hierarchies can result in recommendations that lead to sub-optimal outcomes. All of the relevant interests of the decision maker should be included in the hierarchy and the lower level objectives should be associated with metrics that clearly represent the extent to which that objective is achieved by a decision outcome.

Ideally, metrics should be quantitative and measurable. Some of the metrics adopted for this study were qualitative because time and resource constraints limited the ability to evaluate the metrics quantitatively through modeling studies or other forms of analysis. Metrics should also be meaningful for the stakeholders who are participating in the weight elicitation session. For example, a decision objective to minimize project cost could be represented by a metric that is an estimate of an individual's additional tax burden rather than an estimate of the total project cost, which may hold less meaning for most stakeholders.

All objectives and metrics should be clearly defined. If definitions are long, complicated, or ambiguous, they will lack clarity. Clarity is needed to avoid confusion in the weight elicitation process and divergent views about what a particular metric represents. Such circumstances could undermine the ability to compare weights elicited from stakeholders.

Many different patterns of preference will commonly exist in populations affected by large planning projects. Therefore, it is important that the group of stakeholders who participate in the weight elicitation sessions provide a representative cross-section of the population. If participants are drawn from too narrow a subset of the population, the interests of the population will not be accurately represented.

Preference assessment is a difficult task and it is important that the level of effort needed to obtain valid results not be underestimated. While much effort went into obtaining information on stakeholder preferences for this project, some improvements in the approach are still possible. Stakeholder engagement sessions, such as those conducted for this project, should incorporate controls during the weight elicitation procedure to qualify the results using internal validity tests. For example, future weight elicitation sessions should include tests to help confirm that participants understand and are implementing the instructions properly. In addition, persons conducting the weight elicitation sessions should follow a script so that the procedures are consistently applied from one session to another and are well documented. It may also be useful to expand the scope of information collected from stakeholders. For example, a set of questions unrelated to the project at

hand could assist in developing a more meaningful interpretation of the clusters. This will also provide the ground work for formalizing the MCDA technique and making it more generally applicable to other Corps decision processes.

Finally, there are many uncertainties that can influence a project selection decision. For example, the rate of change in sea-level rise over the life of the project is an obvious and relevant factor to consider in evaluating decision alternatives. Decision analysis assists decision makers in choosing among alternatives despite these uncertainties. Failure to account for uncertainty in the decision can lead to suboptimal outcomes. Therefore, future applications of the RIDF should assess the most important sources of uncertainty and fully analyze their impacts on the decision.

ANNEX 1. – STAKEHOLDER WORKSHOP PARTICIPANTS

Table A1-1.
State Government Participants 10 September. 15 survey participants

Name	Organization
Margaret Bretz	Secretary of State
Mike Buchanan	MS Dept of Marine Resources
Sonia Carr	MEMA Long-Term Recovery
Kerwin Cuevas	MS Dept of Marine Resources
Dale Diaz	MS Dept of Marine Resources
Ashley Edwards	Governor's Office
Tom Mann	MS Museum Natural Science/MDWFP
David McNeel	MS State Port Authority
Jamie Miller	Governor's Office
Ken P'Pool	MS Dept of Archives and History
George Ramseut, Jr.	MS Dept of Marine Resources
David Seyfarth	MS Dept of Transportation
Kathy Shelton	MS Museum Natural Science/MDWFP
R. Chad Wallace	MDOT, Environmental Division
Nick Winstead	MS Museum Natural Science/MDWFP

Table A1-2.
Federal Government Participants 10 September. 11 survey participants

Name	Organization
Valerie Anderson	FEMA Biloxi
Sabrina Chandler	USFWS Jackson
Tyree Harrington	USDA-NRCS
Ntale Kajumba	USEPA Region 4
Rob Lowe	FEMA Region 4
C. Baxter Mann	FEMA-DELO
Bruce McCraney	National Park Service
Jim Murphy	MARAD
Mickey Plunkett	USGS (MS)
Chris Recceston	FEMA
Mark Thompson	National Marine Fisheries Service (Habitat)

Table A1-3.
Local Government Participants 10 September. 8 survey participants

Name	Organization
Patrick Bonck	Harrison County Zoning
Harrietta Eaton	City of Pascagoula
Les Fillingame	City of Bay St. Louis
Liz Ford	City of Pascagoula
Aneice Liddell	City of Moss Point
Gordon Quesenberry	City of Gautier
Jaclyn Turner	City of Pascagoula
Daphne Viverette	City of Moss Point

Table A1-4.
Business/Developer Participants 11 September. 5 survey participants

Name	Organization
Laura Brown	Gulf Coast Investment Dev (GCID)
Willie Davis	City of Pass Christian
Jim Kelly	Eco-Logic Restoration
Shelby Stevenson	CSX Transportation
Stuart Williamson	Association of Floodplain Managers of Mississippi

Table A1-5.
NGO/Scientist Participants 11 September. 5 survey participants

Name	Organization
Jeff Grimes	Gulf Restoration Network
Buck Lawrence	STEPs Coalition/North Gulfport Commission Land Trust
Mike Murphy	The Nature Conservancy
Stephanie Powell	STEPs Coalition Environmental Justice & Sustainability Piller
Judy Steckler	Land Trust

Table A1-6.
Corps MsCIP and ERDC Participants 11 September: 5 survey participants

Name	Organization
Cynthia Banks	ERDC
Todd Boatman	SAM
Barry Payne	ERDC
Susan Rees	SAM
Burton Suedel	ERDC

DRAFT

February 2009

Mississippi Coastal Improvements Program (MsCIP) Hancock, Harrison, and Jackson Counties, Mississippi

Appendix H Barrier Islands

FOREWORD

This document is one of a number of technical appendices to the Mississippi Coastal Improvements Program (MsCIP) Comprehensive Plan and Integrated Feasibility Report and Environmental Impact Statement.

The Mississippi Coastal Improvements Program (MsCIP) Comprehensive Plan Integrated Feasibility Report and Environmental Impact Statement provides systems-based solutions and recommendations that address: hurricane and storm damage reduction, ecosystem restoration and fish and wildlife preservation, reduction of damaging saltwater intrusion, and reduction of coastal erosion. The recommendations contained in the Main Report/EIS also provide measures that aid in: greater coastal environmental and societal resiliency, regional economic re-development, and measures to reduce long-term risk to the public and property, as a consequence of hurricanes and coastal storms. The recommendations cover a comprehensive package of projects and activities, that treat the environment, wildlife, and people, as an integrated system that requires a multi-tiered and phased approach to recovery and risk reduction, irrespective of implementation authority or agency.

The MsCIP Study Area

The purpose of the Comprehensive Plan Report is to present, to the Congress of the United States, the second of two packages of recommendations (i.e., the first being the “interim” recommendations funded in May 2007, and this “final” response, as directed by the Congress), directed at recovery of vital water and related land resources damaged by the hurricanes of 2005, and development of recommendations for long-term risk reduction and community and environmental resiliency, within the three-county, approximately 70 mile-long coastal zone, including Mississippi Sound and its barrier islands, of the State of Mississippi.

This appendix, the Main Report/EIS, and all other appendices and supporting documentation, were subject to Independent Technical Review (ITR) and an External Peer Review (EPR). Both review processes will have been conducted in accordance with the Corps "Peer Review of Decision Documents" process, has been reviewed by Corps staff outside the originating office, conducted by a Regional and national team of experts in the field, and coordinated by the National Center of Expertise in Hurricane and Storm Damage Protection, North Atlantic Division, U.S. Army Corps of Engineers.

The report presents background on the counties that comprise the Mississippi coastline most severely impacted by the Hurricanes of 2005, their pre-hurricane conditions, a summary of the effects of the 2005 hurricane season, problem areas identified by stakeholders and residents of the study area, a summary of the approach used in analyzing problems and developing recommendations directed at assisting the people of the State of Mississippi in recovery, recommended actions and projects that would assist in the recovery of the physical and human environments, and identification of further studies and immediate actions most needed in a comprehensive plan of improvements for developing a truly resilient future for coastal Mississippi.

This appendix contains detailed technical information used in the analysis of existing and future without-project conditions, in the development of problem-solving measures, and in the analysis, evaluation, comparison, screening, and selection of alternative plans, currently presented as tentatively-selected recommendations contained in the Main Report/EIS.

Each appendix functions as a complete technical document, but is meant to support one particular aspect of the feasibility study process. However, because of the complexity of the plan formulation process used in this planning study, the information contained herein should not be used without parallel consideration and integration of all other appendices, and the Main Report/EIS that summarizes all findings and recommendations.

This appendix, The Comprehensive Barrier Island Restoration Plan Appendix, contains detailed supporting data and technical information on the engineering and environmental options that were configured to meet the goals of the Comprehensive Plan. The Comprehensive Barrier Island Restoration Plan was developed through a joint effort of many Federal agencies including the National park Service who has jurisdiction over most of Mississippi's barrier islands as part of the Gulf Islands National Seashore.

EXECUTIVE SUMMARY

Soon after Hurricane Katrina, the notion became widely accepted by the public that if the Mississippi barrier islands had been in a “pre-Hurricane Camille” condition, there would have been much less storm damage during Katrina. During Hurricane Camille, there was extensive land loss on the islands and little natural recovery had occurred since then. Also during Camille, Ship Island was breached and this breach has remained open and is now known as Camille Cut. This massive restoration of the barrier islands was included in the State’s Hurricane Recovery Program which was published soon after Katrina. During completion of the Mississippi Coastal Improvements Program Report, the Mississippi Barrier Islands were subject to several different design concepts for storm damage reduction including total restoration to the pre-Camille condition. These plans are fully described in the Engineering Appendix. Subsequent computer modeling of storm damage reduction benefits from any engineered changes reveal that storm surge reduction was not large, but other benefits would be obtained from simply maintaining the existence of the islands. These benefits include reduction of wave damage to the mainland coast and many important environmental benefits associated with maintaining Mississippi Sound as an estuary formed by the islands. Coordination with the National Park Service (NPS) who has ownership of most of the islands and other agencies has resulted in a plan that will provide continuing existence for the islands that have been badly eroded by storms. Ship Island received sufficient storm damage to endanger it’s survival in the future. This plan, the Comprehensive Barrier Island Restoration Plan, was coordinated with he NPS and includes direct sand placement in the breach of Ship Island with plantings of dune grasses, additional sand placed into the local littoral zone, changes in the Regional Sediment Management Practice, and additional studies of Cat Island where little data is available. The program also has the potential to make beneficial use of dredged material that has been deposited in both inland and offshore areas if quality objectives are clearly demonstrated. After implementation, a long term monitoring program will be established to monitor the project. This data will be extremely valuable in future programs such as this and can provide the NPS with information that they can use to better manage their coastal resources.

Contents

CHAPTER 1 BACKGROUND AND GENERAL INFORMATION 1

CHAPTER 2 NATIONAL PARK SERVICE VISION STATEMENT 3

CHAPTER 3 SEDIMENT TRANSPORT MODELING AND SEDIMENT BUDGET 21

3.1 Introduction and Purpose 21
3.2 Mississippi Coast Physical Setting and Processes 21
3.3 Review of Existing Studies and Dredging Database 24
3.4 Historical Data Analysis 26
3.4.1 Numerical Modeling 28
3.4.2 Sediment Budget 28

CHAPTER 4 INLAND RIVER SAND SOURCES FOR USE AT BARRIER ISLANDS 35

4.1 General Information 35
4.2 Prior "Beneficial Use of Sand" Studies 35
4.3 Additional Studies 36
4.4 References 41

CHAPTER 5 OVERVIEW OF ALL BARRIER ISLAND OPTIONS (LINE OF DEFENSE-1) FROM ENGINEERING APPENDIX 43

5.1 Line of Defense 1 – Offshore Barrier Islands 43
5.1.1 General 43
5.1.2 Restoration of the Offshore Barrier Islands 49
5.1.6 Engineering Options 57

CHAPTER 6 MULTI-AGENCY MISSISSIPPI BARRIER ISLAND RESTORATION RECOMMENDATION 59

6.1 General 59
6.2 Introduction 59
6.3 Background 60
6.3.1 NPS Management of Mississippi Barrier Islands 60
6.3.2 Impacts to Mississippi Barrier Islands and Processes 61
6.4 Barrier Island Restoration Strategy 63
6.4.1 Restoration Goals 63
6.4.2 Emergency Actions 64
6.4.3 Advanced Engineering and Design Actions 65
6.4.4 Long-term Restoration Actions 66
6.4.5 Data Collection, Analysis and Modeling 66
6.5 Adaptive Management Strategies for Mississippi Barrier Island Restoration 67
6.5.1 Monitoring Protocols 67
6.5.2 Barrier Island Restoration Success Benchmarks 68

CHAPTER 7 THE COMPREHENSIVE BARRIER ISLAND PLAN 71

7.1 General 71
7.2 Additional Studies - Littoral Zone Placement and Cat Island Coastal and Ecological Processes and Confirmation of Borrow Areas 72
7.2.1 Confirmation of Offshore Sand Borrow Areas 72
7.2.2 Optimal Littoral Zone Placement 72
7.2.3 Cat Island Coastal and Ecological Processes 72

7.3 Camille Cut and Barrier Island Restoration 72
7.4 Regional Sediment Management Issues 74
7.5 Long Term Monitoring Program 75
7.6 Emergency Sand Placement for Fort Massachusetts and French Warehouse 76

CHAPTER 8 COST ESTIMATES 77
8.1 General 77
8.2 Construction (Sand Placement) Costs 77
8.3 Monitoring Program 77
8.4 Emergency Sand Placement, Fort Massachusetts and French Warehouse 77

CHAPTER 1 BACKGROUND AND GENERAL INFORMATION

The Barrier Island Restoration Plan consists of a comprehensive, all-inclusive plan to construct the best combination of the various options that have been developed for the Mississippi Barrier Islands. The State Plan to "restore the barrier islands to a pre-Camille footprint" offered many different ideas to accomplish this goal. An important factor that was not forgotten during this study was that the Mississippi Barrier Islands are owned within the National Park Service as the "Gulf Islands National Seashore". Coordination with many agencies has resulted in a plan that will provide many benefits including economic, environmental and storm damage reduction. The loss of land mass on the barrier islands has been documented and the continued loss will result in a change in the ecology of the Mississippi Sound that is formed by the island chain. The best method to accomplish any restoration requires that the different options be integrated to maximize benefits and prevent any adverse environmental impacts, modeled to predict the best benefits from any sand placement, and to bring consensus to the many agencies that would be involved in this type of plan. The options discussed in the Engineering Appendix that have been based on three basic concepts for island restoration and identified to include:

- Adding additional land mass to the existing islands by using sand dredged and transported from an off-shore location. The new land mass would be shaped into dunes and marshes and planted with native marsh, maritime forest and dune vegetation or simply planted with these types of vegetation and allowing the effects of nature to create the land forms. The anticipated source of the sand is the St. Bernard Shoals, but this needs further investigation to verify the quantity and quality of the sand.

- Adding sand into the littoral zone at specific locations between the islands based on additional sediment transport modeling. This would allow the littoral currents to move the sand onto the islands where the natural process of island building could take place. This would not directly affect the present-day islands and would help mitigate any effects of dredging the ship channels that pass through the chain of islands where sand may have been lost from the system. This option would obtain the sand from the beneficial use of dredged material from an inland river source or from offshore borrow areas.

- Planting native vegetation to help provide environmental restoration of the existing islands where the vegetation was destroyed by Katrina. These options may also consist of shaping existing sand into low dunes on the beaches or adding sand from an offshore source to create dunes several feet above the existing beach. These dunes would be planted with sea oats to help in the re-establishment of the dunes on the beaches. This would be along with planting of maritime forests in the inland's interior where they were mostly destroyed by Hurricane Katrina. This plan was completed during the fall of 2007 and combined two of the engineering options described in the Engineering Appendix, incorporated some additional studies at Cat Island and recommended changes in the current practices under the Regional Sediment Management Plan. In compiling this plan, several documents were used. In the order included in this appendix is the "National Park Service Vision Statement for the Mississippi Barrier Islands", results of the "Sediment Transport Modeling and Sediment Budget", studies of "Inland River Sand Sources for Use at Barrier Islands", an "Overview of All Barrier Island Options (Line of Defense-1) from Engineering Appendix", and the "Multi-agency Mississippi Barrier Island Restoration Recommendation". The resulting plan is included in Chapter 7 as "The Comprehensive Barrier Island Restoration Plan". After completion of sand placement and planting vegetation, the project will be subject to an 11 year monitoring program described in Chapter 7.

CHAPTER 2 NATIONAL PARK SERVICE VISION STATEMENT

During the study phase for the Barrier Islands, the National Park Service (NPS) issued a Vision Statement for the Mississippi Barrier Islands. As a tool for the planners and engineers, this document set forth the details of any modifications that might be conceived for the barrier islands during this study that would carry the endorsement of the NPS. A copy of this document is included below.

SER-SNRM

JUN 22 2007

Brigadier General Joseph Schrodel
Commander, South Atlantic Division
U. S. Army Corps of Engineers
60 Forsyth Street, Room 9M15
Atlanta, GA 30303-8801

Dear General Schroedel:

As requested by the Mississippi Coastal Improvements Program (MsCIP) Planning Team Program Manager, Dr. Susan Rees, in January 2007, the National Park Service has prepared and is enclosing its "Vision Statement for the Management of the Mississippi Barrier Islands, Gulf Islands National Seashore, National Park Service, June 22, 2007." This document is being copied to the MsCIP Project Delivery Team – Mobile, for incorporation into the draft Comprehensive Plan (MsCIP), which will be released in the fall of 2007 for agency and public reviews fall of 2007.

We appreciate the opportunity to participate in and provide feedback for this important planning process, and we look forward to a continued cooperative relationship with the U.S. Army Corps of Engineers Mississippi Coastal Improvements Program. Please let us know if we can provide additional information.

Sincerely,

Kat Fredrick

Vision Statement for the
Management of the Mississippi Barrier Islands
Gulf Islands National Seashore
National Park Service

June 2007

Executive Summary

The National Park Service (NPS) has a direct interest in the barrier island components of the Mississippi Coastal Improvements Program (MsCIP), since Horn, Petit Bois, East and West Ship Islands, and portions of Cat Island are within Gulf Islands National Seashore (Seashore). The Seashore's purpose is to preserve, protect, and interpret its Gulf Coast barrier island and bayou ecosystem and its system of coastal defense fortifications, while providing for public use and enjoyment. Undeveloped natural resource areas protected by the NPS provide habitat for several endangered species, stop-over habitat for migratory birds, and critical nursery habitat for marine flora and fauna, and serve as an enclave for complex terrestrial and aquatic plant and animal communities that characterize the northern Gulf Coast. The Seashore also contains one of the most complete collections of publicly accessible seacoast defense structures in the United States, from early French and Spanish exploration and colonization through World War II.

Barrier islands are dynamic coastal landforms that act as the interface between ocean and land, and bear the full impact of atmospheric and oceanic energy. Hurricanes, variations in sediment supply, and sea level rise anticipated from global warming will drive changes in island location and morphology. Effective barrier island management requires adaptation to their dynamics.

Based on federal statutes such as the National Park Service Organic Act and the park's enabling legislation, NPS Management Policies, and the Seashore's management plans, the NPS is mandated to preserve natural conditions and processes, and to preserve cultural resources. If peer-reviewed scientific studies indicate that human activities have altered or interfered with natural conditions or processes of the Mississippi barrier islands, such as the natural sediment supply and transport rate and direction, the NPS would consider actions that would attempt to restore those natural processes. Restoration of natural processes would help to re-establish a more natural biological and geological condition within park boundaries.

1

Restoration actions that NPS may consider acceptable and consistent within its legal mandates and authorities are:

Immediate measures (1 year or less)

- Sediment dredged from Ship Island Pass channel should be placed on the beach along the north (sound) shoreline near Fort Massachusetts on West Ship Island. The fort is a listed classified structure on the National Register of Historic Places. Renourishment would better protect the structural integrity of the fort, which currently is threatened by shoreline erosion, migration, and encroachment. Beach renourishment near the documented French Warehouse archaeological site on East Ship Island should also be undertaken, as this site is also currently exposed and threatened by erosion.
- Placement of sand fencing on the upper beach areas of East and West Ship Islands would assist natural dune formation and enhance wildlife habitat. Similar actions would not be appropriate on Horn and Petit Bois Islands given their designation as wilderness areas.
- Planting of sea oats and other native beach grasses and vegetation on East and West Ship Islands would aid the process of natural dune formation.

Long term measures

- Sand dredged from adjacent navigational/shipping channels should be re-deposited within the littoral system of the barrier islands. The additional sand supply would assist the island's natural recovery from recent storm events, and partially offset prior disruption to sediment transport and deposition from past human intervention. The sand must be free from contaminants and compatible in grain size, composition, and color with the existing beach and nearshore sediments.
- A Quality Assurance/Quality Control plan should be developed that includes adaptive management steps to halt, modify or mitigate the effects of activities with negative or adverse impacts to natural or cultural resources.

In order to make informed management decisions, and before beginning long-term measures, the NPS recommends additional scientific study to ensure that actions are effectively targeted and will not harm park resources.

1. Measure bathymetry to 40-ft depth from Dauphin Island to Cat Island, to help develop an improved sediment budget from 1917/20 (the most recent data set with complete bathymetric coverage) to the present.
2. Develop models to predict future location and geometry of the barrier islands at specific time intervals, perhaps 25, 50 and 100 years or longer into the future. Models should include forecasts of sea-level rise linked to global climate change.
3. Assess the quantity of sediment that has entered the Mississippi barrier island system through time from Mobile Pass and the Mobile ebb tidal delta, the primary source of sediment to the barrier islands.
4. Examine barrier island morphologic changes since the 2005 hurricane season to determine the extent of post-storm recovery.

1

I. Introduction

The National Park Service (NPS) has a direct interest in the barrier island components of the Mississippi Coastal Improvements Program (MsCIP). These barrier islands -- Horn, Petit Bois, East and West Ship Islands, and portions of Cat Island -- are all situated within Gulf Islands National Seashore, a unit of the National Park System. NPS also administers the 401-acre Davis Bayou area on the mainland near Ocean Springs, MS.

Gulf Islands National Seashore includes outstanding natural, cultural, and recreational resources along the Northern Gulf of Florida and Mississippi. These include several coastal defense forts spanning more than two centuries of military activity, archeological values, pristine examples of intact Mississippi coastal barrier islands, salt marshes, bayous and submerged seagrass beds, complex terrestrial communities, emerald green water, and white sand beaches.

The barrier islands within the Seashore are nationally significant for several reasons. Specifically, these islands:

1. Contain one of the most complete collections of publicly accessible seacoast defense structures in the United States, representing a continuum of development from early French and Spanish exploration and colonization through World War II.
2. Provide the public with recreational opportunities on natural and scenic island, beach, dune and water areas which possess the rare combination of remaining undeveloped and in a wilderness state, yet are located in close proximity to major population centers.
3. Provide habitat for several endangered species in diverse ecosystems, stop-over habitat for migratory birds, and critical nursery habitat for marine flora and fauna, and serve as an enclave for complex terrestrial and aquatic plant and animal communities that characterize the northern Gulf Coast and fully illustrate the natural processes which shape these unique areas.
4. Contain land and marine archeological resources which represent a continuum of human occupation in a coastal environment and are important in enhancing the knowledge of the past including interactions between the earliest settlers and original inhabitants of this area of the Gulf Coast.
5. Provide a benchmark to compare conditions in developed areas of the Gulf Coast to natural areas within the park.

The NPS manages the Gulf Coast barrier island system in accordance with the various federal laws which govern the National Park System and Gulf Islands National Seashore, NPS national management policies, and park-specific planning and management documents. The NPS management vision for the barrier islands, and several restoration actions potentially consistent with that vision, are explained in Section II. The legal, policy, and administrative authorities which form the foundation of the NPS's vision are explained in Section III. NPS management questions involving further scientific studies

1

are presented in Section IV. The geomorphic origin and history of the island chain are explained in Appendix A.

II. NPS's Vision for the Mississippi Barrier Islands

The NPS's vision for management of the Mississippi barrier islands includes the preservation of natural biological and geological marine and terrestrial conditions and processes, and the preservation of cultural resources, consistent with peer-reviewed and documented scientific study.

Horn and Petit Bois Islands, which are designated wilderness areas, receive an even higher level of protection. In these areas, the NPS vision and management focuses on providing park visitors with an undisturbed environment, a pristine and unencumbered viewshed, an atmosphere of solitude, an opportunity for primitive, unconfined recreation, and negligible evidence of resource impairment. The NPS implements this vision by controlling nonconforming uses, preventing unnecessary or undue reduction of wilderness values, and applying the "minimum requirement" concept of the 1964 Wilderness Act to all proposed projects involving these islands.

The NPS's vision for the Mississippi barrier islands reflects an appreciation for the islands' geomorphic origin and history (see Appendix A). Studies indicate that hurricanes have historically segmented these barriers. A hurricane in 1740 split Isle Dauphin into Petit Bois and Dauphin Islands, while the July 1916 storm cut the Isle of Caprice in two. Furthermore, in 1969, Hurricane Camille split Ship Island into West Ship and East Ship Islands. Hurricanes, variations in sediment supply, and sea level rise anticipated from global warming will drive changes in island location and morphology. Effective barrier island management requires adaptation to their dynamics.

Nonetheless, if peer-reviewed studies provide evidence that human activities have altered or interfered with the natural condition or processes of the Mississippi barrier islands, such as the natural sediment supply and transport rate and direction, the NPS would consider actions that would attempt to restore these natural processes. Restoration of natural processes would, in turn, help to reestablish a more natural biological and geological marine and terrestrial condition within park boundaries, which NPS is charged to promote. Adaptive management principles would govern restoration actions, facilitated by continuing analysis of monitoring data to assess project effectiveness.

The following are restoration actions and associated specifications that NPS may consider acceptable and consistent with the legal mandates and other authorities listed above. NPS restoration actions identified below are contingent upon dedicated funding support for materials and staffing being provided as a component or line item cost incorporated into the MsCIP, as current NPS base funding is insufficient to cover these expenditures.

Immediate measures (1 year or less)

- Sediment dredged from Ship Island Pass channel should be placed on the beach along the north (sound) shoreline near Fort Massachusetts on West Ship Island. The fort is a listed classified structure on the National Register of Historic Places. Renourishment would better protect the structural integrity of the fort, which currently is threatened by active shoreline processes, including erosion, migration, and encroachment. Similarly, beach renourishment near the documented French Warehouse archeological site (GUIS-98, 22Hr-638) on East Ship Island would also be undertaken, as this site is also currently exposed and threatened by erosion due to active shoreline processes.

- Placement of sand fencing behind the upper beach area on both East Ship and West Ship Islands to assist in the process of natural dune formation and enhance wildlife habitat. Specific length and placement design of fencing will be determined in cooperation with park staff. Similar actions on Horn and Petit Bois islands are not feasible considering their designation as wilderness areas, and the coinciding higher conservation standards, and non-manipulative management objectives applying to these areas, as stipulated in Section III, C of this document.

- Planting of sea oats and other native beach grasses and vegetation on East and West Ship Islands as deemed appropriate by park science and natural resources management staff. The native vegetation could also aid in the process of natural dune formation.

Long term measures

- Sediment (sand) dredged from any of the adjacent navigational/shipping channels should be re-deposited within the littoral system of the barrier islands. Sand would be placed to mimic to the greatest extent possible natural sediment depositional processes, including within the surf zones, or as otherwise prescribed based on analysis of the longshore transport system. Sand placement would supplement the supply to the island where it has been significantly diminished or eliminated by dredging of shipping channels, with an estimated withdrawal of ~72 mcy of sand from the system over the last 100+ years. The additional sand supply would assist the island's natural recovery from recent storm events, and partially offset prior disruption to sediment transport and deposition from human-caused intervention.

- Any placement of dredged sediment within the park boundaries, whether on a barrier island beach or within the littoral system, would be contingent upon tests that show that the sediments are free from contaminants and are compatible in grain size, composition, and color with the existing beach and nearshore sediments. Dredging and sediment disposal, which have a significant potential to

5

1

impact many of the animal communities on and around the islands, should be timed to avoid periods of high or seasonal animal activity. Limiting sediment dredging and disposal actions to certain months would reduce or minimize impacts to several threatened and endangered species that spend at least a portion of the year within the barrier island area, as well as non-listed species such as migratory shorebirds which may be particularly sensitive to on-island and nearshore disturbances.

- A Quality Assurance/Quality Control (QA/QC) plan should be developed, possibly as part of the NEPA or environmental compliance process, to monitor both adverse and beneficial impacts of any activities undertaken within the boundaries of GUIS as part of the MSCIP. The QA/QC plan should include monitoring during construction activities to measure immediate or short-term impacts, as well as for a specified time period after construction activities are completed to measure long-term or cumulative impacts. The plan should also include adaptive management steps to halt or modify activities, or to mitigate the effects of activities, should negative or adverse impacts to natural or cultural resources be noted during monitoring. The QA/QC plan would be developed through coordination between the US Army Corps of Engineers, National Park Service, the US Fish and Wildlife Service and the National Marine Fisheries Service.

III. Statutory, Policy, and Administrative Foundation of the NPS Vision for the Mississippi Barrier Islands

The NPS vision for managing the Mississippi barrier islands is derived directly from the federal laws which govern the National Park System and Gulf Islands National Seashore. Because Horn and Petit Bois Islands are also designated wilderness areas, the NPS's vision for these islands is additionally derived from the law which established the National Wilderness Preservation System.

A. Statutory Basis for NPS Management of the Mississippi Barrier Islands

In the **National Park Service Organic Act of 1916** (16 U.S.C. § 1), Congress stated that "There is hereby created in the Department of the Interior a service to be called the National Park Service, which shall be under the charge of a director....The service thus established shall promote and regulate the use of the Federal areas known as national parks, monuments, and reservations hereinafter specified, except such as are under the jurisdiction of the Secretary of the Army, as provided by law, by such means and measures as conform to the fundamental purpose of the said parks, monuments, and reservations, which purpose is to conserve the scenery and the natural and historic objects and the wild life therein and to provide for the enjoyment of the same in such manner and by such means as will leave them unimpaired for the enjoyment of future generations."

1

Subsequently, in the **National Park System General Authorities Act of 1970**, Congress clarified that national park areas are to be "preserved and managed for the benefit and inspiration of all of the people of the United States, in light of the high public value and integrity of the National Park System" (16 U.S.C. § 1a-1). In the **National Parks Omnibus Management Act of 1998,** Congress instructed the NPS to integrate the results of scientific research into its management decisions (16 U.S.C. § 5936).

In the **enabling legislation which established Gulf Islands National Seashore**, Congress instructed the NPS to preserve for public use and enjoyment the outstanding natural, historic, and recreational values of the area, including wildlife natural resources and the military forts within the park (16 U.S.C.§ 459h). Congress further stipulated that "[t]he Secretary of the Interior and the Secretary of the Army may cooperate in the study and formulation of plans for beach erosion control and hurricane protection of the Seashore. Any such protective works or spoil deposit activities undertaken by the Chief of Engineers, Department of the Army, shall be carried out within the seashore in accordance with a plan that is acceptable to the Secretary of the Interior and that is consistent with the purposes of sections 459h to 459 h-10 of this title."

As required by the **Endangered Species Act of 1973** (16 U.S.C. § 1531 et seq.), the NPS also strives to conserve threatened and endangered species at Gulf Islands National Seashore, ensuring that its authorization, funding, or implementation of activities will not jeopardize the existence of any endangered or threatened species of plant or animal (including fish) or result in the destruction or deterioration of critical habitat of such species.

The Mississippi barrier islands also contain a number of sites of historic/archaeological value, including Fort Massachusetts on West Ship Island, which is a listed classified structure on the National Register of Historic Places. The NPS preserves these cultural resources and landscapes as required by the **National Historic Preservation Act** (16 U.S.C. § 470 et seq.).

Additionally, Horn and Petit Bois islands are designated wilderness areas and are therefore subject to the provisions of the **Wilderness Act of 1964** (16 U.S.C. §§ 1131, 1133), which directs federal land management agencies to preserve the wilderness character of the areas, including the preservation of natural conditions with the imprint of man's work substantially unnoticeable.

B. Policy Basis for NPS Management of the Mississippi Barrier Islands

The NPS's management vision for the Mississippi barrier islands is additionally derived from the Service-wide NPS Management Policies. Updated in 2006 after extensive review and comment from the general public, the scientific community, and agency employees, the NPS Management Policies are mandatory for all NPS employees unless specifically waived or modified in writing by the Secretary of the Interior, the Assistant Secretary of the Interior, or the Director of the National Park Service.

1

The sections of the NPS Management Policies most relevant to NPS management of the Mississippi barrier islands are quoted here. The policies are available in their entirety at www.nps.gov/policy/mp/policies.html or www.nps.gov/policy/MP2006.pdf.

(1) Section 4.4.2.4: Management of Natural Landscapes

"Natural landscapes disturbed by natural phenomena, such as landslides, earthquakes, floods, hurricanes, tornadoes, and fires, will be allowed to recover naturally unless manipulation is necessary to (1) mitigate for excessive disturbance caused by past human effects, (2) reserve cultural and historic resources as appropriate based on park planning documents, or (3) protect park developments or the safety of people. Landscape and vegetation conditions altered by human activity may be manipulated where the park management plan provides for restoring the lands to a natural condition."

(2) Section 4.8.1.1: Shorelines and Barrier Islands

"Natural shoreline processes (such as erosion, deposition, dune formation, overwash, inlet formation, and shoreline migration) will be allowed to continue without interference. Where human activities or structures have altered the nature or rate of natural shoreline processes, the Service will, in consultation with appropriate state and federal agencies, investigate alternatives for mitigating the effects of such activities or structures and for restoring natural conditions…Any shoreline manipulation measures proposed to protect cultural resources may be approved only after an analysis of the degree to which such measures would impact natural resources and processes, so that an informed decision can be made through an assessment of alternatives. Where erosion control is required by law, or where present developments must be protected in the short run to achieve park management objectives, including high-density visitor use, the Service will use the most effective method feasible to achieve the natural resource management objectives while minimizing impacts outside the target area."

(3) Section 4.1.5: Restoration of Natural Systems

"The Service will reestablish natural functions and processes in parks unless otherwise directed by Congress. Landscapes disturbed by natural phenomena, such as landslides, earthquakes, floods, hurricanes, tornadoes, and fires, will be allowed to recover naturally unless manipulation is necessary to protect other park resources, developments, or employee and public safety. Impacts on natural systems resulting from human disturbances include the introduction of exotic species; the contamination of air, water, and soil; changes to hydrologic patterns and sediment transport; the acceleration of erosion and sedimentation; and the disruption of natural processes. The Service will seek to return such disturbed areas to the natural conditions and processes characteristic of the ecological zone in which the damaged resources are situated. The Service will use the best available technology, within available resources, to restore the biological and physical components of these systems, accelerating both their recovery and the recovery of landscape and biological community structure and function."

(4) Section 4.4.1: General Principles for Managing Biological Resources

"The National Park Service will maintain as parts of the natural ecosystems of parks all plants and animals native to park ecosystems….by

8

1

- preserving and restoring the natural abundances, diversities, dynamics, distributions, habitats, and behaviors of native plant and animal populations and the communities and ecosystems in which they occur; …. and
- minimizing human impacts on native plants, animals, populations, communities, and ecosystems, and the processes that sustain them."

(5) Section 4.4.2.3: Management of Threatened or Endangered Plants & Animals

"The Service will survey for, protect, and strive to recover all species native to national park system units that are listed under the Endangered Species Act. The Service will fully meet its obligations under the NPS Organic Act and the Endangered Species Act to both proactively conserve listed species and prevent detrimental effects on these species."

(6) Section 4.6.4: Floodplains

"In managing floodplains on park lands, the National Park Service will (1) manage for the preservation of floodplain values; (2) minimize potentially hazardous conditions associated with flooding; and (3) comply with the NPS Organic Act and all other federal laws and executive orders related to the management of activities in flood-prone areas, including Executive Order 11988 (Floodplain Management), the National Environmental Policy Act, applicable provisions of the Clean Water Act, and the Rivers and Harbors Appropriation Act of 1899."

(7) Section 4.6.5: Wetlands

"The Service will manage wetlands in compliance with NPS mandates and the requirements of Executive Order 11990 (Protection of Wetlands), the Clean Water Act, the Rivers and Harbors Appropriation Act of 1899, and the procedures described in Director's Order 77-1 (Wetland Protection). The Service will (1) provide leadership and take action to prevent the destruction, loss, or degradation of wetlands; (2) preserve and enhance the natural and beneficial values of wetlands; and (3) avoid direct and indirect support of new construction in wetlands unless there are no practicable alternatives and the proposed action includes all practicable measures to minimize harm to wetlands."

(8) Sections 6.1, 6.3.3, 6.3.5, & 6.3.7: Wilderness Management

These sections direct the National Park Service to manage wilderness areas for the use and enjoyment of the American people in such a manner as will leave them unimpaired for future use and enjoyment as wilderness. They further charge the NPS to (1) administer designated wilderness lands consistently among agencies but in no way diminish any established NPS wilderness standards and values.; (2) keep human-caused intrusions within wilderness to an absolute minimum; (3) ensure proposed actions are narrow in scope and the least required to effectively preserve wilderness character; and (4) apply science-based decision making in all NPS wilderness areas.

(9) Sections 5.3.5, 5.3.5.1, 5.3.5.1.1-4: Cultural Resources

Recognizing that the NPS is the steward of many of America's most important cultural resources, including archeological sites, as well as historic and prehistoric structures, the NPS Management Policies specify that park cultural resource management involves: (1)

1

research to identify, evaluate, document, register, and establish basic information about cultural resources and traditionally associated peoples; (2) planning to ensure that management processes for making decisions and setting priorities integrate information about cultural resources and provide for consultation and collaboration with outside entities; and, (3) stewardship to ensure that cultural resources are preserved and protected, receive appropriate treatments to achieve desired conditions, and are made available for public understanding and enjoyment.

C. Administrative Planning Basis for NPS Management of the Mississippi Barrier Islands

In 1978, Gulf Islands National Seashore produced a General Management Plan (GMP) which provides long-term direction for administering the Seashore. Congress requires each park unit to have a GMP to guide park decisions about resource preservation, visitor use, and park management. GMPs are developed and adopted with much public review and input. Gulf Islands National Seashore is developing a new General Management Plan, which is anticipated to be completed in 2009-2010. Until then, the existing 1978 GMP, its 1983 amendment, and a 1995 updated Statement for Management will remain in effect.

As directed by the 1978 GMP, the NPS must manage the Mississippi barrier islands in the following ways:

- Keep development to a minimum, and manage Petit Bois and Horn Islands as wilderness areas emphasizing their primitive character and limited development.
- Promote diverse marine biota in Mississippi Sound, and the surrounding Gulf of Mexico waters and diverse estuarine biota at Davis Bayou, and assure that activities within the Seashore have the least possible effect on the population of fish, shellfish, and other marine and estuarine organisms.
- Minimize disturbance of natural landforms, vegetation, and wildlife by human-caused activities and restoring ecological conditions on lands adversely affected by such uses and activities in the past.
- Protect and perpetuate the Seashore's natural resources and managing them in ways that enhance natural, ecological, and geological processes and mitigate the adverse effects of human activities.
- Perpetuate suitable habitat conditions to support the Seashore's rich flora and fauna, with particular emphasis on Federally or State endangered or threatened species or, other species of management concern.
- Allow for the natural processes of storms and hurricanes related to barrier island development, by minimizing construction and development of facilities in areas prone to natural channelization and overwash, or otherwise dynamically active.

NPS management of Horn and Petit Bois Islands is also based on the Congressionally-mandated Wilderness Management Plan, completed in 2004. In accordance with this plan, the NPS objectives for these island wilderness areas are to (1) provide for solitude and primitive, unconfined recreation; (2) preserve the character of the wilderness, including a pristine, unencumbered viewshed; and (3) control nonconforming use and

1

prevent unnecessary or undue reduction of wilderness values. The plan further establishes that the NPS's desired future condition for Horn and Petit Bois Islands is a wilderness area unaffected by the works and acts of humankind, where minimum tools or techniques are used in the completion of any project.

IV. Information Needs for NPS Management

The questions listed below were developed by NPS to highlight perceived scientific data needs and research gaps with respect to geomorphology issues to be addressed for NPS to make informed management decisions as to potential restoration alternatives for the barrier islands as part of the MsCIP. The study needs following the questions identify studies and research likely to yield data that could be used to address NPS management needs framed in the questions. The study needs should be regarded as only an initial list, and NPS would welcome the opportunity to work with the Army Corps of Engineers and the U.S. Geological Survey, as well as other agencies, to further refine these study needs.

A. NPS Scientific Data/Research Questions

1. To what extent have human-caused actions, principally from dredging of shipping channels in proximity to the MS barrier islands, altered the sediment transport and depositional processes of the islands?
2. Taking a modeling approach, what would the configuration/make-up of the MS barrier islands be today had sediment transport processes not been disrupted through human intervention, including reoccurring dredging to maintain adjacent shipping channels?
3. Taking a modeling approach, what is the projected future (25, 50, & 100-year intervals) configuration/make-up of the barrier islands given existing conditions vs. what the islands may otherwise look like if natural processes, including hurricane effects, were the only contributing factor to island migration historically and over time?
4. Factoring in the unpredictability of climate change and sea level rise, as well as hurricane frequency, what is the projected future location and configuration of the barrier islands (25, 50, & 100-year intervals)? The modeling studies should use both the long-term relative sea-level rise for the area, as well as one or more increased rates of sea-level rise as predicted with global climate warming data.
5. Given the present sediment transportation and depositional processes, where might additional sand be introduced into the active coastal system to most effectively maintain the MS barrier islands?

B. Further Study Needs

1. Measurement of the present-day bathymetry to a 40-ft depth for the Mississippi barrier island area from Dauphin Island to Cat Island. The most recent bathymetric data from 1960/1971 included only limited

1

coverage offshore of the barrier islands. More extensive coverage of the present-day bathymetry could be used to formulate an improved historical sediment budget from 1917/20 (the most recent data set with complete bathymetric coverage) to the present. Measurement of the present-day bathymetry would allow the ongoing dredging and placement activities around Ship Island Pass and Horn Island Pass to be incorporated into the sediment budget.

2. Modeling studies to predict future location and geometry of the barrier islands at various scenarios of sea level rise. Existing information on historical shoreline change, bathymetric change, and dredging records, as well as any additional present-day bathymetric data that could be collected, may also be utilized in the studies that would predict future change in the barrier islands at specific time intervals (perhaps 25, 50, 100 years or longer) in the future. The modeling studies should use both the long-term relative sea-level rise for the area, as well as one or more increased rates of sea-level rise as predicted with global climate warming data.
3. Better understanding of the quantity of sediment that has entered the Mississippi barrier island system from Mobile Pass and the Mobile ebb tidal delta, the origin of the sediment supply to the barrier islands. A sediment budget should be developed for the Dauphin Island area that would quantify sediment transport from Mobile Pass and the Mobile Pass ebb tidal delta to Dauphin Island, and from Dauphin Island westward towards Petit Bois Island. A historical sediment budget could be developed based on existing bathymetric change, shoreline position change and dredging records. A hypothetical present-day sediment budget could also be developed based upon present-day bathymetric data and shoreline positions, incorporating dredging activities in and around Mobile Pass.
4. Studies to examine barrier island morphologic changes since the 2005 hurricane season to help determine the extent of storm recovery. Studies may use a combination of data sets, and include for example, the present-day bathymetry and hypothetical sediment budget. Full LiDAR (scanning airborne laser altimetry) and aerial video and photography coverage of the islands could be collected and compared with post-Katrina data collected in 2005 to quantify changes in elevation and shoreline position. Precise shoreline position and elevation data may also be collected in the field using high resolution GPS ground surveys to verify the laser altimetry data. These data sets may help identify the most effective locations and quantities of additional sediment to be introduced into the barrier island littoral system.

1

Appendix A
Geomorphology of the Mississippi Barrier Islands

Barrier islands are extremely dynamic coastal landforms. They act as the interface between ocean and land, and bear the full impact of atmospheric and oceanographic energy. Composed primarily of sand and water, the features and habitats of the islands are constantly changing and evolving through time. The following excerpt from the Geologic Resource Evaluation Scoping Summary for Gulf Islands National Seashore (KellerLynn, 2007) briefly describes the origin and history of the Mississippi barrier islands located within the seashore.

The six barrier islands along the Mississippi Sound are parallel to the Pleistocene mainland coast (fig. 1). Dauphin Island, the only island not part of the national seashore, is at the mouth of Mobile Bay; westward are Petit Bois, Horn, East Ship, West Ship, and Cat islands. The sound behind the islands is very wide, more than 7 miles (11 km) on average, and deepens gradually from the mainland shore to the islands, with depths exceeding 20 feet (6.1 m) locally (Kwon, 1969).

As in Florida, the barrier islands in Mississippi formed from shoals (Otvos, 1979). Natural interactions between relative sea level, sediment supply, and meteorological-oceanographic conditions, and human-induced changes from dredging, sediment diversion, and habitat modifications resulted in the present configuration (Schmid, 2003). According to Otvos and Giardino (2004), the earliest barrier islands emerged between 5,700 and 5,000 years ago, when sea level was lower than present by 3.2 to 4.9 feet (1.0–1.5 m).

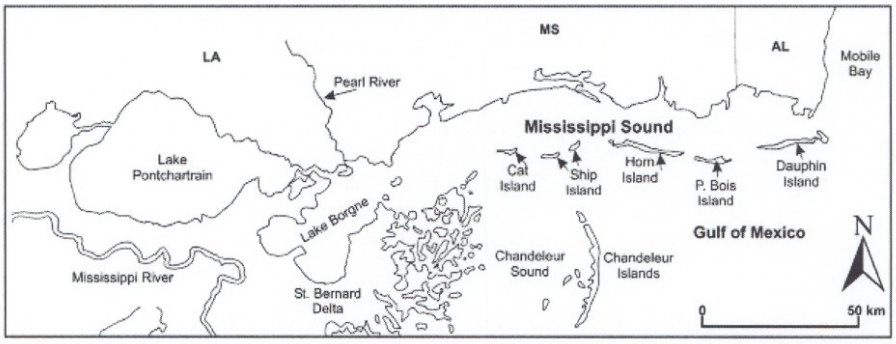

Figure 1. Index map of major landforms in the Mississippi Sound barrier island chain. *Source*: Otvos and Giardino (2004).

The islands formed against a background of decelerating late Holocene sea-level rise. At this time, eastern Dauphin Island represented a higher Pleistocene ground that was veneered by Holocene beach and dune deposits. Dauphin Island became the transmission site for large volumes of littoral sand. From this small island, the rest of Dauphin Island

aggraded and extended westward as a narrow, shore-parallel sandy shoal platform (Otvos and Giardino, 2004). By "capturing" the sand that arrived from the Alabama mainland shore through current and drift processes via the Mobile Bay ebb-tidal delta and steering it westward along its south shore, eastern Dauphin Island probably played an important role in originally determining the general offshore position of the whole barrier island chain, which extended well into southeastern Louisiana (Otvos and Giardino, 2004). Many new barrier sectors formed downdrift by gradual extension over adjacent shoal platform areas.

Historic trends indicate that island reduction by storm and fair-weather erosion to subtidal levels alternated with periods of platform aggradation above low-tide level. For instance, the earliest islands and beach ridges of still existing islands east of Cat Island were replaced by shoal areas or more recent islands (Otvos, 1981). Square Handkerchief Shoal west of and aligned with Cat Island probably represents the platform of an extinct barrier (Otvos and Giardino, 2004). Between 3,500 and 4,000 years ago, the St. Bernard delta of the Mississippi River (see fig. 1) prograded into the area west of the Mississippi barrier islands. Mainland extension and marsh development as a result of this progradation stranded the barrier islands and halted their westward migration. Sediments from the delta created shoals in present-day Mississippi Sound, which interrupted westward-directed littoral drift, diminished the impact of the Gulf wave regime, and deactivated Cat Island and the Square Handkerchief Shoal by approximately 2,400 years ago. Cat Island, its sand supply from the other islands cut off by surrounding shoal waters, kept eroding on its eastern end. Shore erosion, combined with subsidence, eliminated the oldest ridge sets off northern Cat Island long ago (Otovs, 1979). Another example of periodic erosion and aggradation is "Isle of Caprice," which existed between Horn and "Ship" islands between the early 1900s and 1940. This island and its neighboring group of islands ("Dog Keys") had a history of emergence, punctuated by episodes of these islets becoming shoals (Otvos, 1979; 1981).

The erosive history of the island chain suggests a relatively short life expectancy (Otvos and Giardino, 2004). French and British charts from the 18th century indicate that Dauphin and Petit Bois islands once formed a single entity ("Isle Dauphin") (Otvos, 1979). The oldest (eastern) part of Petit Bois Island formed the western sector of this ancient island that also incorporated present-day Dauphin Island. After Petit Bois and Dauphin were separated, Petit Bois gradually lost its narrow eastern sector. Widening to a record 5.3 miles (8.5 km) by 1957, Petit Bois Pass now overlaps with the former island area. Since the 1850s, Petit Bois has prograded westward, in downdrift direction (Otvos, 1979). While Petit Bois advanced approximately 3.1 miles (5.0 km) westward between 1850 and 1974, its 9.6-mile- (15.5 km) long eastern sector reverted to a shoal platform. Chart and survey data document a 26% area reduction in Ship, Horn, and Petit Bois islands, declining from a combined surface area of 15.5 square miles (40.2 km^2) in 1850 to 11.5 square miles (29.7 km^2) in 2000 (Otvos and Giardino, 2004).

Although episodic, hurricane destruction and segmentation have played an essential role in the evolution of all the Mississippi Sound barriers (Otvos, 1979) (see "Hurricane-generated Features" section). For instance, during the 1740 hurricane, Isle Dauphin was

1

separated into Petit Bois and Dauphin islands (Otvos, 1979); Isle of Caprice was cut in two by the July 1916 hurricane (Otvos, 1979); and Ship Island was split into West Ship and East Ship islands during Hurricane Camille in 1969 (Falls, 2001). In 2005, Hurricane Katrina completely submerged the entire barrier island chain, segmenting several of the islands and causing significant erosion.

CHAPTER 3 SEDIMENT TRANSPORT MODELING AND SEDIMENT BUDGET

3.1 Introduction and Purpose

In order to conceive any realistic plan for island restoration, it is necessary to understand the physical processes that move sand along the littoral drift zone off the coast of Mississippi. This littoral zone influences the character of the Mississippi barrier islands as they exist in an ever-changing cycle. To help in this understanding, a sediment transport model was conducted to establish a sediment budget for the islands. This study evaluated the existing regional sediment transport magnitudes and directions for the Mississippi and Alabama barrier islands fronting Mississippi Sound and the mainland coast, including an analysis of historical long-term barrier island migration. Based on analysis of previous studies, historical bathymetric and shoreline change, and numerical modeling, a suite of sediment budgets was developed. First, a conceptual sediment budget was developed through a review of existing studies; this budget formed the framework for the historical and calculated sediment budgets. Next, a historical sediment budget was developed through analysis of bathymetric and shoreline position change through time. Engineering activities and significant storm events were also documented. A calculated sediment budget was developed based on numerical modeling of regional waves and sediment transport, for the Gulf and Bay shorelines of the barrier islands as well as the mainland coast. The final sediment budget was formulated from all these intermediate budgets, and is presented herein along with a summary of information pertinent to the final budget. Details about the conceptual, historical, and calculated sediment budgets and further discussion of the entire study can be found in the draft Regional Sediment Budget for Mississippi Mainland and Barrier Island Coasts, Rosati et al. (2007) attached at the end of this appendix. Volume change and sediment budget calculations in the 2007 draft MsCIP sediment budget report will be updated during the advanced engineering and design phase using the Jan 2008 upgrade to ESRI's ArcGIS. This recent software upgrade allows more accurate procedures for quantifying volumetric change than were applied when the report was originally written in the spring of 2007. These changes are not likely to impact overall trends in the regional sediment transport system, but may change the magnitude of volumetric differences.

3.2 Mississippi Coast Physical Setting and Processes

The barrier islands in the project area, Cat, West and East Ship, Horn, Petit Bois, and Dauphin Islands, provide the offshore boundary for Mississippi Sound (Figure 3.2-1). These islands are the first line of defense for the mainland as tropical storms, hurricanes, and cold fronts pass the region. Table 3.2-1 summarizes the tropical storm and hurricane history for locations in and around the study area from 1871 (or 1872) through 2006. Because data were not provided for a city in Hancock County, New Orleans, Louisiana is shown in Table 3.2-1 to provide a western boundary to the study area. Locations in Hancock County are assumed to have storm occurrences similar to those presented for New Orleans and Gulfport.

[1] http://www.hurricanecity.com/. This database does not have any locations in Hancock County, Mississippi; thus, data for New Orleans, Louisiana are included to provide a western boundary for the study area. Locations in Hancock County are assumed to have storm occurrences similar to those provided for New Orleans and Gulfport.

The frequency of direct landfall is approximately equal for Biloxi, Pascagoula, and Dauphin Island, with a direct hit every 10-11 years. The likelihood for a direct hit decreases to approximately once every 15 and 12 years for Gulfport and New Orleans, respectively. However, all locations listed in Table 3.2-1 have historically been brushed or hit with a tropical storm or hurricane approximately once every 3-4 years. Cold fronts, although less intense than tropical storms and hurricanes, occur more frequently at approximately 30 to 40 times per year (Stone et al. 1999).

The barrier islands protecting Mississippi Sound experience a low energy wave climate, with average significant wave height at National Data Buoy Center (NDBC) Buoy 42007 (22 nautical miles south-southeast of Biloxi, in 46 ft depth) averaging 2 ft and 1.3 ft in the winter and summer months, with associated average peak wave periods of 4 to 3.5 sec, respectively. Wave transformation modeling by Cipriani and Stone (2001) indicated that breaking wave heights on the barrier islands range from 1 to 2 ft. Waves in Mississippi Sound are fetch- and depth-limited. The Coastal Studies Institute's Wave-Current Surge Information System (WAVCIS[1]) gage CSI-13 located at Ship Island Pass (23 ft depth) from June 1998 through July 2005 measured an average significant wave height of 0.3 ft and associated average wave period of 2.5 sec.

Tides in Mississippi Sound are diurnal, with a tidal range of 1.5 ft and 1.8 ft for the mean and spring tides at Biloxi, Mississippi[2], respectively. However, the relatively shallow and large area of the Sound create strong currents in the tidal passes between the barrier islands, ranging from 1.63 to 3.3 ft/sec and 5.9 to 11.5 ft/sec on flood and ebb tides, respectively (Foxworth et al. 1962). In the winter months, winds from the same direction and of a sufficient magnitude are capable of lowering water surface elevations in the bays and nearshore from 1-2 ft (U.S. Army Corps of Engineers Mobile District 1984).

For the Gulf barrier island beaches, net longshore sediment transport is from east to west, although local reversals in the net transport occur adjacent to the tidal passes. The primary sources of sediment are longshore sediment transport from east to west, and, potentially, the offshore shelf (Otvos 1979, Cipriani and Stone 2001). Cipriani and Stone (2001) discussed that a well-defined cellular structure exists for each barrier island in which, over historic times, little sand transfer exists between islands. However, dredging records at Horn Island and Ship Island Passes (also called Pascagoula Bar Channel and Gulfport Bar Channel, respectively) suggest that infilling of sand from adjacent barrier islands occurs, indicating the potential for transport of sand between islands. Eastern Dauphin Island, with a Pleistocene core, is more stable than the other barriers although eastern Dauphin Island has been eroding in response to the dominant westerly-directed transport. Based on grain size analysis, Cipriani and Stone (2001) inferred that offshore sources may provide some sediment to central Petit Bois Island. The Mississippi Sound barrier islands range from very well vegetated, with maritime forests on east Dauphin Island, to low elevation barriers that are overwashed and breached during hurricanes. Long-term relative sea level rise for Dauphin Island, Alabama from 1966 to 1997 was 0.12 +/- 0.023 in/year[3].

On the mainland coast, beach change in Harrison County has been dominated by harbor construction, beach restoration and replenishment since 1951 (Byrnes et al. 1993a, 1993b). Cross-shore sediment transport processes dominate beach change, with wave-induced sediment transport processes of secondary importance, typically from east-to-west (Byrnes et al. 1993a, 1993b). Hancock County had beach nourishment in 1993-1994 between Waveland and Bay St Louis and again in 1996 for the Bay St Louis Downtown beach (Schmid 2002). Net longshore transport in Hancock County is generally from northeast to southwest. The bays, distributaries, and bayous of

the remaining coast are typically bordered with marsh populated by *Spartina-Juncus* succession (Christmas 1973).

3.3 Review of Existing Studies and Dredging Database

Existing studies were reviewed for the project area to provide information about sediment transport processes of the barrier island and mainland coast. This knowledge gained was incorporated into the sediment budget as appropriate. For a full summary of each study that was reviewed, please see Rosati et al. (2007).

Dredging rates for navigation channels within Mississippi Sound were also evaluated in the study. As was shown in Figure 3.2-1, the study area is traversed by many navigation channels: two "bar" channels that extend through Horn Island Pass (also called Pascagoula Bar Channel) and Ship Island Pass (also called Gulfport Bar Channel); the Gulf Intercoastal Waterway (GIWW) that runs east-west through Mississippi Sound; and five Sound navigation channels that extend from Gulfport, Biloxi, Pascagoula, Bayou Cassotte, and Bayou La Batre. The SAM dredges these channels on a regular basis. The U.S. Army Corps of Engineers' Navigation Data Center[4] (NDC) has documented all Corps contract and non-contract dredging for all Districts for Fiscal Year (FY) 1990 through 2005. NDC's database for SAM's entire District dredging program is provided in Rosati et al. (2007).

Byrnes and Griffee (2007) culled historical dredging and placement information from published Corps reports and databases to develop annual dredging and placement rates for each of the bar channels. Sediment dredged from the GIWW and other channels extending through Mississippi Sound was side-cast or placed in disposal areas to either side of the channels, and is assumed to shoal primarily from fine sediment that is mobilized in the bay. Thus, these dredging and placement activities in the Sound do not change the sediment budget for the mainland and barrier islands. However, dredging and placement adjacent to the barrier islands (Ship Island Pass/Gulfport Bar Channel and Horn Island Pass/Pascagoula Bar Channel) must be considered in the sediment budget.

Dredging data provided by Byrnes and Griffee (2007) have been analyzed to provide estimated maintenance shoaling rates for each of the Bar Channels as a function of channel depth, width, and length (Table 3.3-1). Of particular interest is the maintenance dredging rate as a function of channel depth, as shown in Figure 3.3-1.

Table 3.3-1.
Summary of Dredging Rates for Navigation Channels Adjacent to Barrier Islands (modified from Byrnes and Griffee 2007)

Date	Description	New Work (cy)	Maintenance (cy)
Ship Island Pass/Gulfport Bar Channel (Data from 1881-2003)			
Mar 1899–Mar 1948	26-ft deep, 300-ft width, 0.76-mile long channel (1.9-mile length dredged in 1922)	163,401	2,115,576 (43,175 cy/yr) (33,028 cu m/yr)
Mar 1948–Jul 1992	32-ft deep, 300-ft wide, 8 miles long	3,679,044	21,111,495 (476,200 cy/yr) (364,292 cu m/yr)
Nov 1993–Apr 2003	38-ft, 300-ft wide, 8 miles long	9,695,988	5,456,817 (579,485 cy/yr) (443,306 cu m/yr)

[4] http://www.iwr.usace.army.mil/NDC/data/datadrg.htm , updated 25 July 2006, accessed 13 December 2006.

Table 3.3-1.
Summary of Dredging Rates for Navigation Channels Adjacent to Barrier Islands
(modified from Byrnes and Griffee 2007)

Date	Description	New Work (cy)	Maintenance (cy)
1899 to 2003	**Total Dredging**	**13,538,433**	**28,683,888 (275,807 cy/yr) (210,992 cu m/yr)**
Horn Island Pass/Pascagoula Bar Channel (Data from 1881-2005)			
Feb 1897–Mar1948	25-ft deep, 300-ft wide channel	896,748	1,735,817 (34,000 cy/yr) (26,010 cu m/yr)
Mar 1948–Jan 1965	38-ft deep, 325-ft wide, 2.8 mile length	2,910,835	2,711,925 (161,104 cy/yr (123,245 cu m/yr)
Jan 1965–Sep 1993	40-ft deep, 350-ft wide; Impoundment area along the western end of Petit Bois Island	1,305,589	14,772,517 (515,320 cy/yr) (394,220 cu m/yr)
Sep 1993–Nov 2005	44-ft deep, 550-ft wide; Impoundment area along the western end of Petit Bois Island	3,117,658	2,986,712 (245,483 cy/yr) (187,690 cu m/yr)
1897 to 2005	**Total Dredging**	**8,230,830**	**22,206,971 (205,600 cy/yr) (157,284 cu m/yr)**

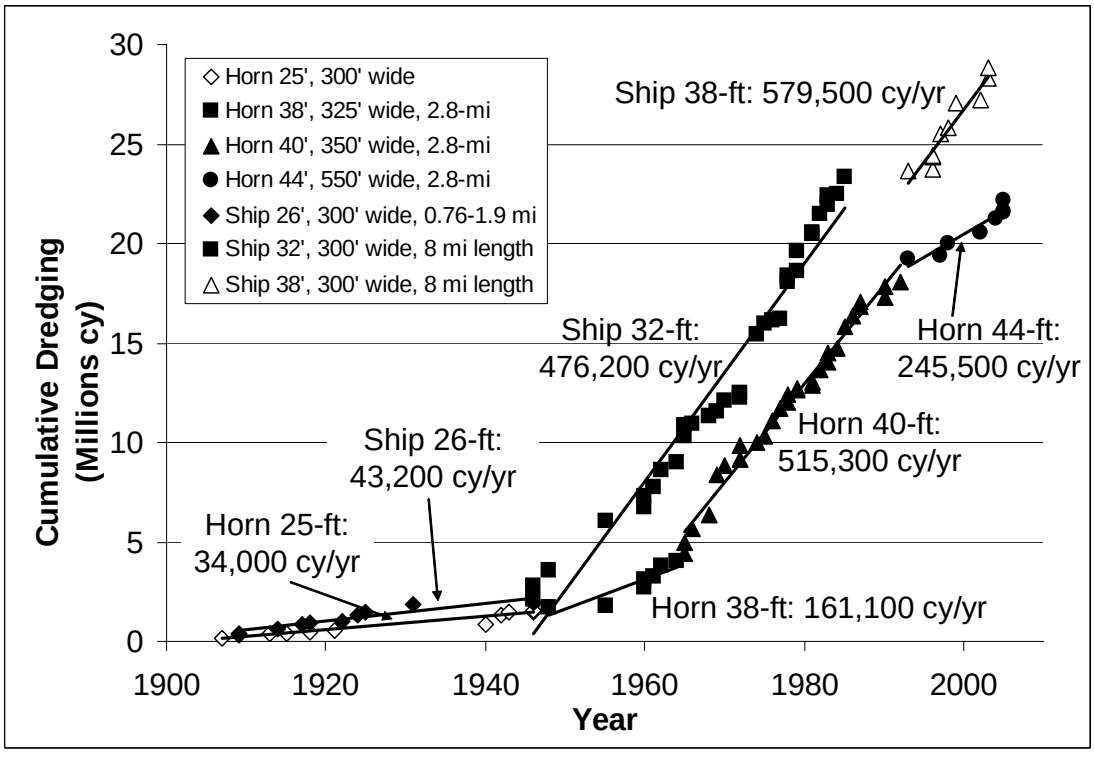

Figure 3.3-1. Cumulative maintenance dredging volumes and associated dredging rates for Horn Island Pass (Pascagoula Bar Channel) and Ship Island Pass (Gulfport Bar Channel)

These data indicate that deepening Ship Island Pass in 1948 by 23% (from 26 to 32 ft depth) and lengthening the channel (from 0.76 and 1.9 miles to 8 miles) increased the maintenance dredging rate by more than an order of magnitude (from 43,200 to 476,200 cy/yr). Dredging rates also increased more than an order of magnitude at Horn Island Pass through several depth increases from 25 to 40 ft, an increase in width from 325 to 350 ft, and length to 2.8 miles (dredging increased from 34,000 to 515,300 cy/yr). However, the dredging rate at Horn Island Pass decreased most recently when the channel was deepened to 44 ft and widened to 550 ft. This decrease in shoaling is opposite to what would be expected and possibly indicates a change in dredging or placement practices at Horn Island Pass. As these channels were deepened, they were also lengthened to provide safe navigation from a similar depth contour offshore. Thus, the deeper channels not only provided a better trap for sand moving alongshore but also resulted in longer channels which captured more of sand that is being transported in the offshore zone.

As mentioned previously, dredging for channels in the Sound do not modify the sediment budget for the barrier islands and mainland coast. The NDC's dredging database has been evaluated to provide a complete regional sediment budget as shown in Table 3.3-2.

Table 3.3-2.
Dredging Rates for Navigation Channels in Mississippi Sound (from SAM and NDC Database)

Location	Dates	Duration (years)	Shoaling Rate (cu yd/yr)	Notes
Gulfport Harbor Channel[1]	Jul 1991 – Sep 2004	8.3	1,151,000	Assume includes GIWW dredging
Biloxi Harbor Channel	Dec 1991 – Aug 2003	12.5	43,600	
Pascagoula Harbor Channel	Aug 1992 – Jan 2005	13.5	3,074,600	Assume includes GIWW dredging in vicinity of Pascagoula
Bayou Cassotte	Sep 1992 – Sep 2000	8	248,500	
Bayou La Batre	May 1996 – Sep 2004	8.3	732,400	Assume includes GIWW dredging

[1] Omitted Gulfport deepening in 1992.

3.4 Historical Data Analysis

A second phase of this study developed a historical sediment budget for the barrier islands and adjacent passes based on bathymetric change, shoreline position change, and dredging and placement data. The historical sediment budget is utilized to develop the present-day sediment budget. In this chapter, historical volumetric change, shoreline position change, and dredging data are reviewed. This portion of the study was conducted by Byrnes and Griffee (2007).

Shoreline and bathymetric data were compiled within a Geographic Information System (GIS) for the Mississippi Sound region. This database has associated metadata specifying the coordinate system, vertical datum, measurement units, and timing of data collection for each data set. Data are available for 1846/57, 1916/21, and 1960/71 periods, with coverage of the eastern portion of the study area available for 1984/89.

The primary goal of bathymetric change analysis is to identify regional sediment transport pathways and quantify net sediment volume changes associated with the historical evolution of nearshore morphology and adjacent beaches. Table 3.4-1 provides a summary of bathymetric data available for the Mississippi Sound area. Initial bathymetric surveys of the area were completed for the period 1847/56. All data have been compiled within a GIS framework, so metadata regarding coordinate

system, vertical datum, measurement units, and timing of data collection are provided in the attribute table for each data set. These data, in addition to recorded shoreline changes, have been used to quantify regional sediment dynamics throughout the study area and evaluate the historical sediment budget for the period 1917/21 to 1960/71. Limited coverage offshore of Horn, Petit Bois, and Dauphin Islands for the 1960/71 period limits volumetric change calculations and, ultimately, the historical sediment budget.

Table 3.4-1.
Bathymetry Source Data Characteristics (from Byrnes and Griffee 2007)

Date	Data Source	Comments and Map Numbers
1847/56	USC&GS Hydrographic Sheets 1:20,000	First regional bathymetric survey within the study area. 1847 - H-00191; 1847/48 – H-00192; 1848 – H-00193, H-00194; 1851 – H-00256, H-00261; 1852 – H-00329; 1853 – H-00328, H-00365; 1854 – H-00430; 1855 – H-00485, H-00488, H-00489; 1856 – H-00546.

1984/89	USC&GS Hydrographic Sheets 1:20,000 (D-00079, F-00324, H-10179, H-10208, H-10226, H-10247, H-10261) 1:40,000 (D-00078, H-10206) 1:80,000 (D-00065)	Survey covering eastern portion of the study area; 1984/87 - D-00065, D-00078; 1985/87 - H-10179; 1985 - H-10206, H-10208; 1986/88 – H-10226; 1987 - H-10247, H-10261; 1988 - D-00079; 1989 - F-00324.

Several insights into forcing processes and engineering activities were observed from the bathymetric change data.

(1) Overall, the barrier islands have eroded on the eastern regions and accreted to the west, indicating the dominant direction of longshore sand transport from east-to-west. Similarly, the Passes between barrier islands have also migrated to the west, as noted by the ebb shoal that erodes to the east and reforms to the west. Thus, the migrating barrier islands naturally “push” the Passes to the west.

(2) Dredging of the ship channels in Mississippi Sound is readily observed in the bathymetric change maps that include the 1960/71 surface, with side-casting and placement of the dredged material shown on either side of the channels. This side-cast sediment does not appear to move within Mississippi Sound.

(3) As the barrier islands have eroded, portions of the barriers have rolled over towards the Sound. For example, East Ship Island and western Dauphin Island have eroded on the Gulf side and reformed in a more northerly location further into the Sound. The processes transporting sand into the Sound is a combination of overwash during storms and inlet formation and possible subsequent closure.

(4) Portions of the barrier islands are relatively stable and maintain position through time (this is observed in Byrnes and Griffee’s (2007) shoreline position data). Examples of these locations are

the widest portions of Horn, Petit Bois, and Dauphin Islands. These areas are likely more stable ancient Pleistocene formations along which the sand spits which comprise the rest of the barrier island morphology form.

(5) Cat Island is not part of the sand-sharing system that comprises Dauphin, Petit Bois, Horn, and Ship Islands and the Passes that separate these barrier islands. Cat Island is a separate entity and the bathymetric change maps do not indicate that sand from Ship Island naturally bypasses or transports to Cat Island. If there were connectivity between Ship and Cat Island, it would be evidenced by erosion or accretion of morphologic features between the islands.

(6) From the historical shoreline position data (Byrnes and Griffee 2007), it is evident that the barrier islands have experienced cycles of breaching and mending throughout history. For example, Dauphin Island breached in 1917 in response to the 1915 hurricane, and reformed by 1957 slightly further northward (into the Sound) at the location of the washover deposit. Dauphin Island again shows a breach in the 2006 shoreline position data. Similarly, Ship Island breached in response to the 1947 hurricane and the barrier had reformed by 1950. Ship Island has been divided into East and West Ship Islands since another breach formed in the 1960s. These cycles of breaching and reformation indicate that breaches will naturally mend through the dominant longshore sand transport direction to the west, if a sufficient source of sediment is available. The historical data analysis is further discussed in Byrnes and Griffee (2007) and Rosati et al. (2007).

3.4.1 Numerical Modeling

Two numerical models were applied to develop estimates of sediment transport magnitudes and pathways. First, GENESIS shoreline change modeling that was conducted as a part of a larger regional study was incorporated to provide potential longshore sand transport rates for the Gulfside of the barrier islands for representative yearly waves. This model used pre-Katrina shoreline positions. Next, regional wave transformation modeling was conducted with STWAVE to estimate breaking wave height and direction magnitudes for the Gulfside and mainland coast beaches. These wave parameters and the shoreline orientation for sections of the Gulf barrier beaches and mainland coast were used to calculate potential longshore sand transport rates. Potential longshore sand transport rates are those estimated to occur if a sufficient quantity of sand were available for transport. Thus, these calculations do not apply to muddy coastlines or wetland regions of the study area. Finally, STWAVE was also applied to estimate wind-induced wave parameters for the Sound side of the barrier islands and subsequent sand transport on the Sound barrier coast. The methodology and results for this numerical modeling are discussed in Rosati et al. (2007).

3.4.2 Sediment Budget

Using the calculated and historical sediment budgets, and dredging and placement practices from 1993-2005 as presented by Rosati et al. (2007), a present-day (post-Katrina shoreline position) sediment budget has been hypothesized. In formulating this budget, several assumptions were made as follows:

(1) The historical sediment budget (1917/20-1960/71) was weighted more heavily than the calculated sediment budget, because the historical budget is based on actual measured changes in the region. However, for portions of the barrier islands that have changed morphology since the 1917/20 to 1960/71 period, or would be modified by a change in dredging or placement practices, the calculated sediment budget was given preference. The calculated sediment budget was adopted for eastern Dauphin Island because volume change data have not yet been released, pending acceptance of the Dauphin Island mitigation study.

(2) In the absence of historical data, the calculated sediment budget and observed morphologic response were adopted for the mainland coast.

(3) Dredging and placement practices from 1993 to 2003/2005 were adopted for Ship Island Pass and Horn Island Pass, and the barrier island response to these activities was hypothesized. Dredging rates for Gulfport, Biloxi, and Pascagoula Harbor Channels, and Bayou Cassotte and Bayou La Batre were adopted as shown in Table 3.3-2. The source of sediment for these channels in Mississippi Sound was assumed to be fine-grained sediment that is mobilized during storms and wind events.

The hypothetical present-day sediment budget is shown in Figures 3.4-1 through 3.4-10, in which P=placement of dredged material, R=dredging or removal of sand, and sand fluxes are shown in thousands of cubic yards per year. It is emphasized that this sediment budget is only one of many possible solutions that could represent typical present-day conditions.

Knowledge gained through this study and recommendations that follow include the following:

(1) Cat Island is not a part of the barrier island littoral system represented by Dauphin, Petit Bois, Horn, and East and West Ship Islands. Cat Island is a separate morphologic feature that is naturally eroding due to waves, storm surge, and relative sea level rise in the region. Dredged sand that is placed in the littoral zone to the west of Ship Island Pass most likely will not be transported to Cat Island. Even in the absence of any engineering activities in Mississippi Sound, there is no evidence that sand from Ship Island would ever reach Cat Island.

(2) The net longshore sand transport rate for the barrier islands is from east-to-west. The barrier islands are migrating towards the west and, as they move west, also move the Passes between islands in a westerly direction. The source of sand for this region is the Mobile Pass ebb tidal shoal and the sandy shelf and shoreline to the east of Mobile Pass. Ship Island is the terminus of the longshore sand transport system in this region. Thus, the regional shortage of littoral sand will be most profoundly observed at Ship Island. Disintegration of this barrier island, especially since Hurricane Katrina in 2005 has been observed. It is also recommended that restoration of any barrier

islands in Mississippi Sound begin with Ship Island. Also recommended is back-passing sand dredged from Ship Island Pass, placing this sand either in Camille Cut, near East Ship Island, or in Dog Keys Pass. Sand can be placed in the surf zone (3 to 6-ft depths) and the natural longshore sand transport process will rebuild the island and begin to mend breaches.

(3) The historical sediment budget from 1917/20 to 1960/71 includes bathymetry change, shoreline position change, and dredging and placement practices representative of this period. However, data for the 1960/71 period are very sparse offshore of the barrier islands. This lends some uncertainty to the historical budget. In addition, Ship Island Pass and Horn Island Pass were deepened (and Horn Island was widened) in 1992/1993. Since that time, dredging rates have increased from those that occurred during the 1917/20 to 1960/71 period. Thus, the historical sediment budget is not representative of present-day dredging and placement activities, and has uncertainty with respect to bathymetric change offshore of the barrier islands. We recommend measurement of modern bathymetry (to 30 or 40-ft depths) and formulation of a sediment budget characterizing the period from 1917/20 (which has sufficient bathymetric coverage) to present-day.

(4) The historical analysis indicated that Horn Island has not experienced wash-over deposition across the entire island and has only been breached on a part of terminal spit during Hurricane Katrina (personal communication, Ms. Linda Lillycrop, May 2005). This cross-shore stability implies that the elevation and width of this barrier island might be a good template to evaluate for possible future restoration of the Mississippi Sound barrier islands.

(5) Wave modeling indicated that the mainland coast experiences a greatly reduced wave climate due to sheltering by the barrier islands fronting Mississippi Sound, as well as the Chandeleur Islands, and the Mississippi River's Bird's Foot delta. Restoration of the barrier islands could also consider lengthening the islands to recreate a previous historical footprint to provide additional wave protection for the mainland coast.

CHAPTER 4 INLAND RIVER SAND SOURCES FOR USE AT BARRIER ISLANDS

4.1 General Information

While off-shore sources of good quality sand exist, other inland sources of sand exist that could be used for barrier island restoration. After the construction of inland waterways in Alabama and Mississippi, maintenance dredging is required to maintain the channel depths and alignments. This material is typically moved to disposal areas along the banks of the river where it accumulates in diked areas. Dredging of some of the areas along the river produces large quantities of sand that have potential use for beach nourishment. An inventory of current disposal sites indicates that approximately 30,000,000 cubic yards of sand may be available. Only disposal sites that contain a minimum of 100,000 cubic yards of sand were included in the inventory. Of interest to this study are disposal sites that are located along the Black Warrior–Tombigbee River system and the Tennessee-Tombigbee Waterway. Figure 4-1 shows the relationship of these disposal areas to the project sites along the Mississippi coast. Material from these sites could easily be transported by barge down the river system for use along the beaches.

4.2 Prior "Beneficial Use of Sand" Studies

Because of the shortage of additional disposal areas, the Corps of Engineers' Operations Division has contracted for several studies on the beneficial use of the sand. Some of these studies have been targeted at using the sand for beach nourishment, (Thompson Engineering, 2001). Using sand samples from some of the inland disposal areas along the Black Warrior – Tombigbee River, a series of analyses were conducted on the samples. For comparison purposes, several samples of actual beach sand and from the littoral drift zone from coastal Alabama were taken and subjected to the same tests. These tests included grain size distribution (gradation), color and roundness. The results of the tests indicated that some of the samples may be suitable for beach nourishment. The sand samples from the river were typically a finer grain size that the beach sand with the predominant river size being a fine sand while the beach sand was mostly medium sand. It was also noted that the beach sand was slightly more rounded than the river sand.

The one factor that warranted further analysis was the color difference of the river sand as compared to the beach sand. All of the river sand had a brown tint described as "very pale brown" or "light yellow brown". This compared to the beach sand samples which were described as "pale olive, white or light grey". These colors were assigned along with evaluations for hue, value and chroma from a Munsell Soil Color chart which provides a standard method of assigning color to soils. These reports also indicated that the color may be due to staining on the sand grains and not included in the mineral structure of the sand itself. The report also noted that beach sand came from a higher energy environment where any staining due the depositional environment may have been removed by abrasion due to wave action. It also noted that the sand might undergo bleaching from the ultraviolet radiation from the sun if the color was caused by a mineral staining. To test these conditions that may change the color of the sand, a series of tests were conducted on samples from the same areas that were used during the initial analyses, (Thompson, 2002). The samples were subjected to two tests. The first involved actual bleaching of the samples using a chemical oxidizer, hydrogen peroxide, for different periods of time. These tests did indicate that the bleaching process was detectable after 72 hours. Other tests were conducted to simulate the process of wave action causing an agitation of the particles which may remove any mineral coating or staining along with

exposure to ultraviolet light. This process was conducted for 144 hours without a notable difference in color.

Other studies on the dredge disposal areas by the Bureau of Mines, U.S. Department of the Interior were conducted to characterize the sand for use as an aggregate in making concrete (Smith, 1995). While these tests were not directed at use of the sand for beach nourishment, they did supply information on chemical and physical characteristics of the materials from several locations. These tests provided data that shows the sand to be clean, mostly fine grained, quartz sand with little of no fines, to be non-toxic based on Toxic Characteristic Leachate Procedure (TCLP) and to contain very little heavy minerals. All of these tests would indicate the material would be safe to place on a beach.

Review of the documents referenced above indicated that the color issue was not resolved and this would be an important factor in the use of the sand on the barrier island beaches. The methods employed, bleaching and agitation with exposure to ultraviolet light, were not considered to be effective in removal of what is suspected to be the basis of the color on the sand grains, amorphous iron oxide more commonly referred to as rust. Hydrogen peroxide is a common household bleaching agent that is effective in oxidation of organic matter, but would no effect iron oxide through chemical removal. The same is true for the effects of ultraviolet light on iron oxide. The idea of using agitation would be the most effective of the methods attempted if the color was a coating on the mineral grains, but the test, as conducted, was not conclusive.

4.3 Additional Studies

With the renewed interest in the possibility of using the sand as a source of material for the littoral zone associated with the Mississippi barrier islands, the disposal areas warranted further study. Again the color of the sand is a concern that has been raised by the National Park Service who has control of the Mississippi Barrier Islands. This concern has both aesthetic and environmental aspects. Aesthetically, the beaches on the barrier islands are composed of relatively white sand. Numerous studies have indicated that the primary source of this sand is an Appalachian origin probably associated with river systems discharging onto the Continental Shelf of present-day Florida (Stone and Others, 2004). This sand is transported westward from the discharge of the river into the Gulf of Mexico. Transport of this sand along the prevailing littoral current has created the white beaches and barrier islands that extend from Florida westward across Alabama to Mississippi as shown in Figure 4-2.

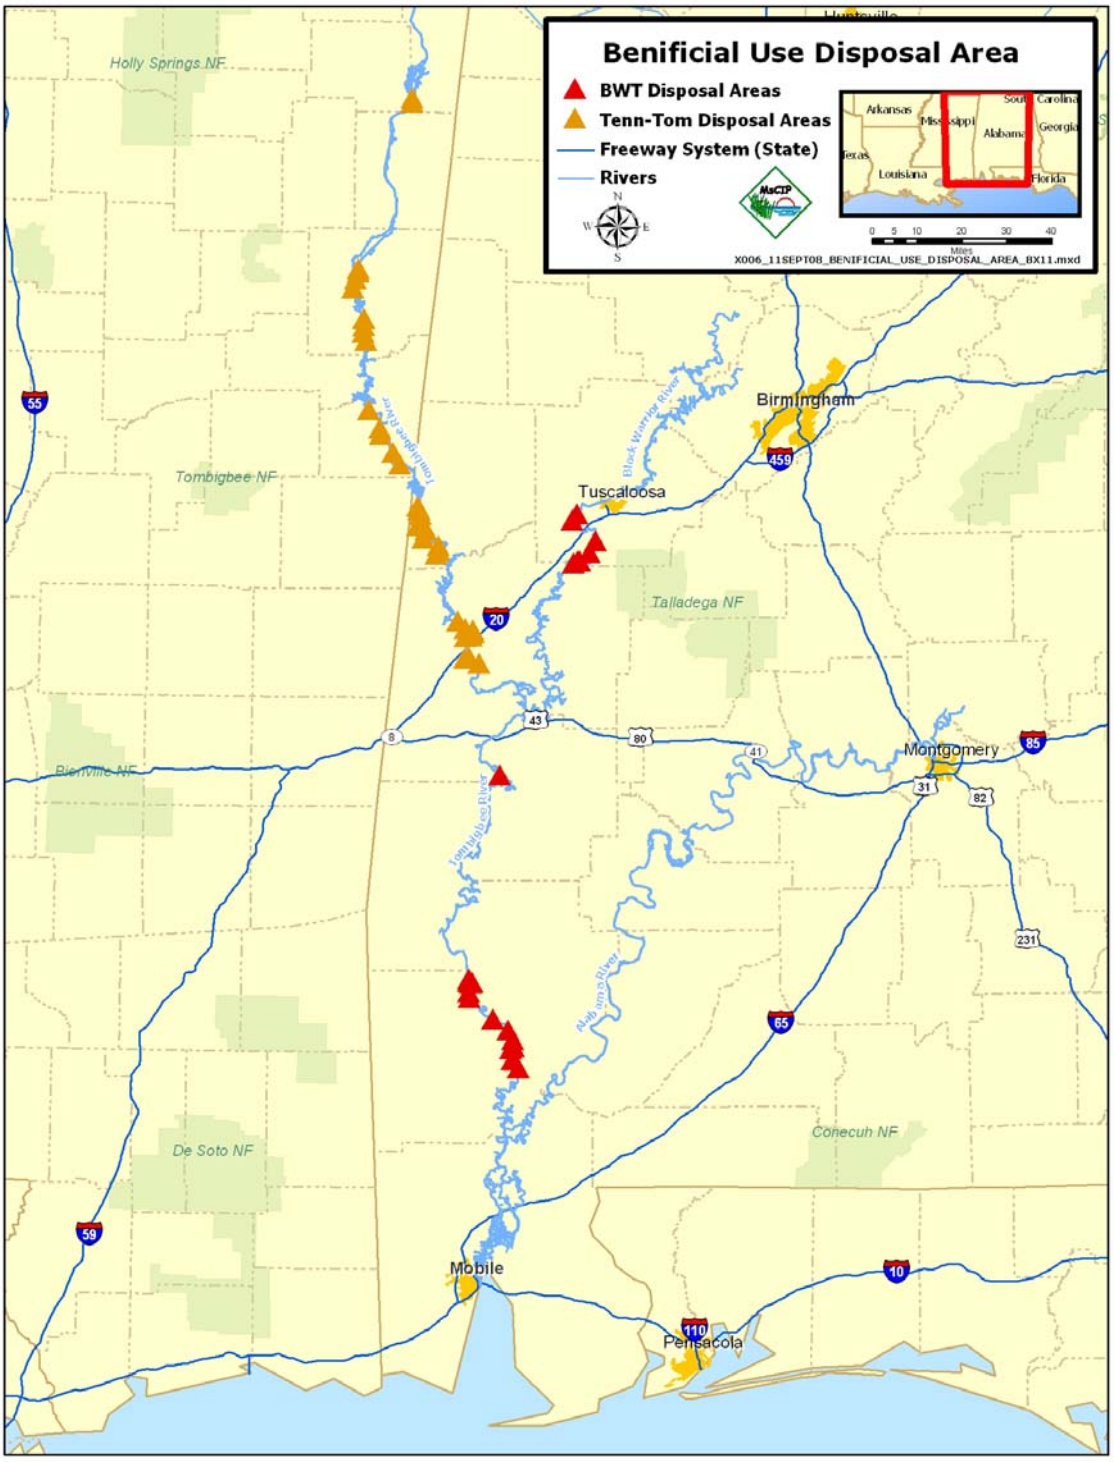

Figure 4-1. Location of Disposal Areas Along the Black Warrior–Tombigbee River System and the Tennessee-Tombigbee Waterway

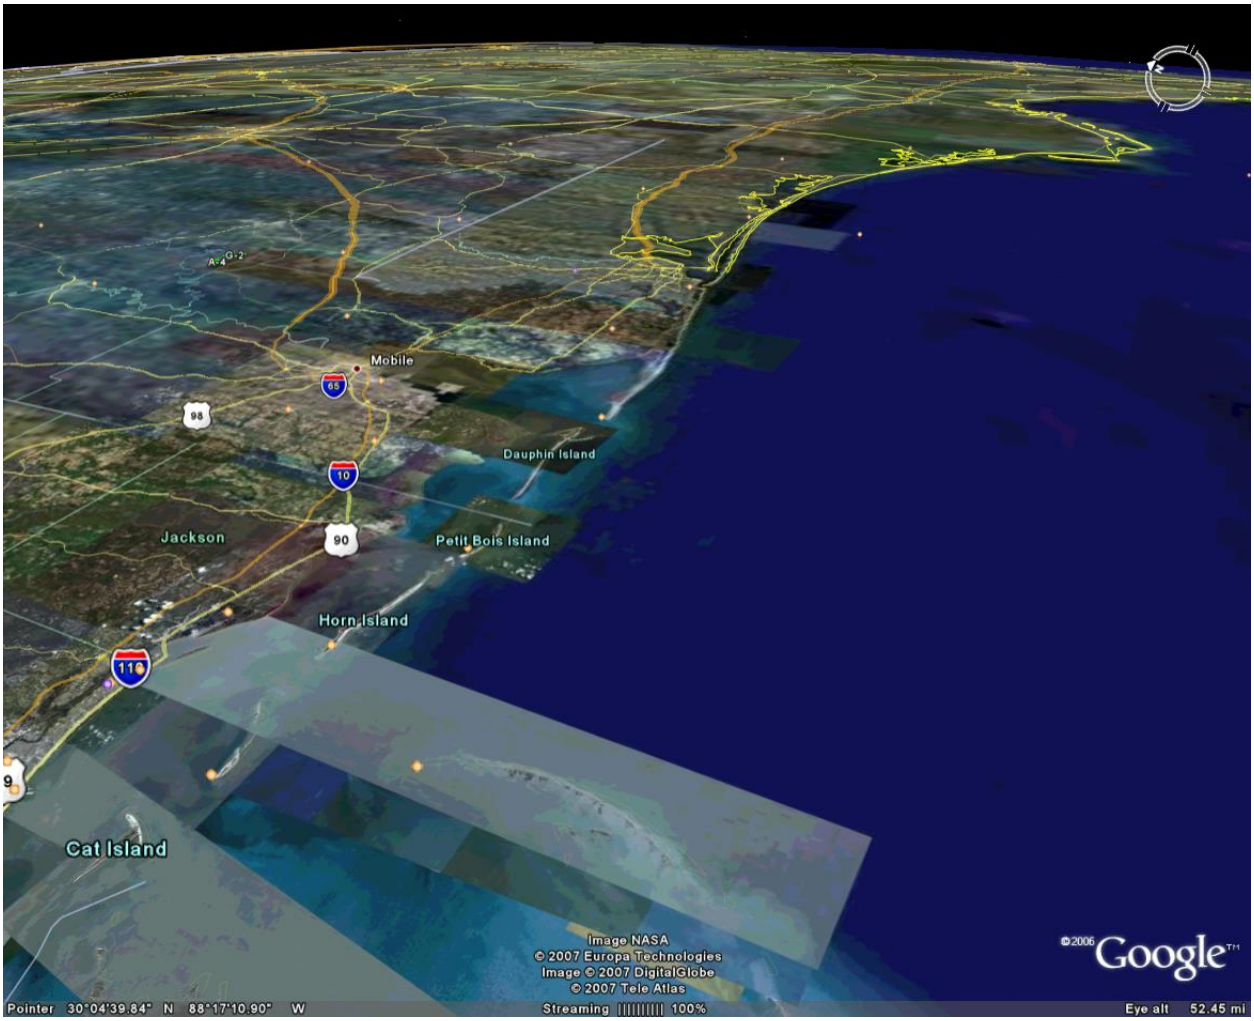

Figure 4-2. Littoral zone (white beaches and islands) along Central Gulf Coast extending from Bay County, Florida (top of picture) to Mississippi Barrier Islands (lower left), looking east.

Looking at the color differences of the sand along this system reveals a definite change as shown in Figure 4-3. The sample on the left was taken from sand dredged from the Chattahoochee River which is a major tributary of the Apalachicola River. This sampling location is approximately 150 river miles above the Gulf. The middle sample was taken from Disposal Area 39 on the Apalachicola River approximately 37 river miles above the Gulf. The sample on the right was taken from the south beach of Petit Bois Island in Mississippi. Note the progressive change in color from brown to tan to white.

Geochemical processes could account for the consistent staining of the sand grains while in the river system. As the sand entered the Gulf's littoral system, changes in the geochemical process would not allow additional staining of the sand and any removal of the coating would allow the underlying sand grain to display its true color. The mechanical process of abrasion would occur both in the river system and the littoral system, but if the iron oxide staining was continuously reoccurring in the river system, the resulting color would remain. As the sand grains entered a different geochemical environment where re-staining did not occur, it would account for the difference where the color was a coating. Review of selected sand samples taken from the Black Warrior– Tombigbee River system disposal areas the reveal the same general color that is characteristic of the Chattahoochee-Apalachicola River system. Figure 4-4 is a photograph of five samples that include the same

samples used in Figure 4-3 plus two additional samples, one from the Black Warrior River and another from the Tombigbee River. Note the similarities in color of the Apalachicola River (fourth from left), the Black Warrior (third from left and marked BWT North Star), and the Lower Princess (second from left, Lower Tombigbee River).

Figure 4-3. Samples of Sand taken from (left to right) Chattahoochee River Mile 150, Disposal Area #39 on the Apalachicola River, and Petit Bois Island

Figure 4-4. Samples of Sand taken from (left to right) Chattahoochee River Mile 150, Disposal Area #39 on the Apalachicola River, North Star Disposal Area on the Black Warrior River, Lower Princess Disposal Area on the Tombigbee River, and Petit Bois Island in Mississippi

Assuming that the previous testing was not effective at removing the iron oxide staining on the sand grains, a different bench-top test was performed. If iron oxide is only a coating on the sand grains and occurs as a stain, abrasion would be effective in the removal. The addition of a week acid would also aid in keeping the iron oxide from re-coating the sand grains as it is being removed. For the experiment, I used a small "rock tumbler" of the type used to polish small stones. Into the chamber of the rock tumbler was added a small quantity of sand obtained from the Lower Princess disposal area on the Tombigbee River, enough water to just cover the sand and a tablespoon of "Zud". Zud is a household cleaning product that is composed of oxalic acid and abrasives. Oxalic acid is a weak acid commonly used to remove rust stains. Zud contains about 10% oxalic acid and 90% fine abrasives. The tumbling chamber was closed and placed the tumbler. An electric motor spins the chamber which allows the contents to tumble. This process would mimic the process of sand grains being transported along the littoral zone with the sand grains being abraded as they strike each other. In the almost infinite volume of water in the Gulf, any iron stain that was removed would not re-coat the sand, but be diluted away. This process started on 4 October 2007 and concluded 10 October 2007. The tumbler did not run over the included long weekend, but did operate for about 4 days. At the completion of the tumbling process, rinse water was added and decanted several times until the turbidity levels dropped and the fines were removed. The remaining sand was air dried and placed in a clear plastic bag for comparison with sand from the same parent sample. As shown in Figure 4-5, the results of the experiment are quite dramatic. The tumbled sand lost most of the tan color and is approaching white. This supports the process that occurs with the tan sand from the Apalachicola River system becoming the white sand so familiar to beach-goers along the central Gulf Coast.

Figure 4-5. Samples of Sand taken from (left to right) North Star Disposal Area on the Black Warrior River, Lower Princess Disposal Area, and "Tumbled Lower Princess Disposal Area"

Adding the sand into the littoral system along the gulf coast could provide the proper geochemical and mechanical processes to remove the iron staining and provide the quality of sand that is desired as it is transported along the littoral drift zone which contain the Mississippi Barrier Islands. Littoral zone placement will also allow additional sorting by the currents and rounding of the sand grains through continued abrasion during transport. Additional research and testing will be performed to support this process prior to any use of any sand from disposal areas.

CHAPTER 5 OVERVIEW OF ALL BARRIER ISLAND OPTIONS (LINE OF DEFENSE-1) FROM ENGINEERING APPENDIX

5.1 Line of Defense 1 – Offshore Barrier Islands

5.1.1 General

The coastline of mainland Mississippi is bordered on the south by the Mississippi Sound, a shallow body of water that separates the coast from four barrier islands that lie several miles to the south as shown in Figure 5.1.1-1. These barrier islands are located along a littoral drift zone that moves sand westward creating three elongated islands and then westward toward Cat Island, where littoral currents are not as well defined. The birds-foot delta system from the Mississippi River has extended through the historic littoral system, cutting off the sediment transport. Cat Island had the same origin than the other islands, but now being re-shaped by wave action and lack of new sediments moving into the system. Wave action has created a beach on the eastern side of the island forming a distinctive T-shape. From west to east, the islands are Cat, Ship (now actually two islands, West and East Ship Island), Horn and Petit Bois. As noted above, Ship Island has been breached by prior hurricanes and now is actually two small islands, West Ship Island and East Ship Island, with a shallow sand bar between the two. Since Hurricane Camille in 1969, this breach has existed with varying amounts of natural rebuilding between later storms and is now known as Camille Cut. The western ends of both Petit Bois and West Ship Islands have migrated westward and are now against maintained deep-water navigation channels and the continuing littoral drift of the sand into the channels is causing an artificial termination of the migration. A small, new island has emerged on the west side of the channel from Petit Bois Island, created from the dredged sand that is disposed of on the west side of the channel. This small island can be seen in Figure 5.1.1-1 as the small island just west of and across the channel from Petit Bois Island.

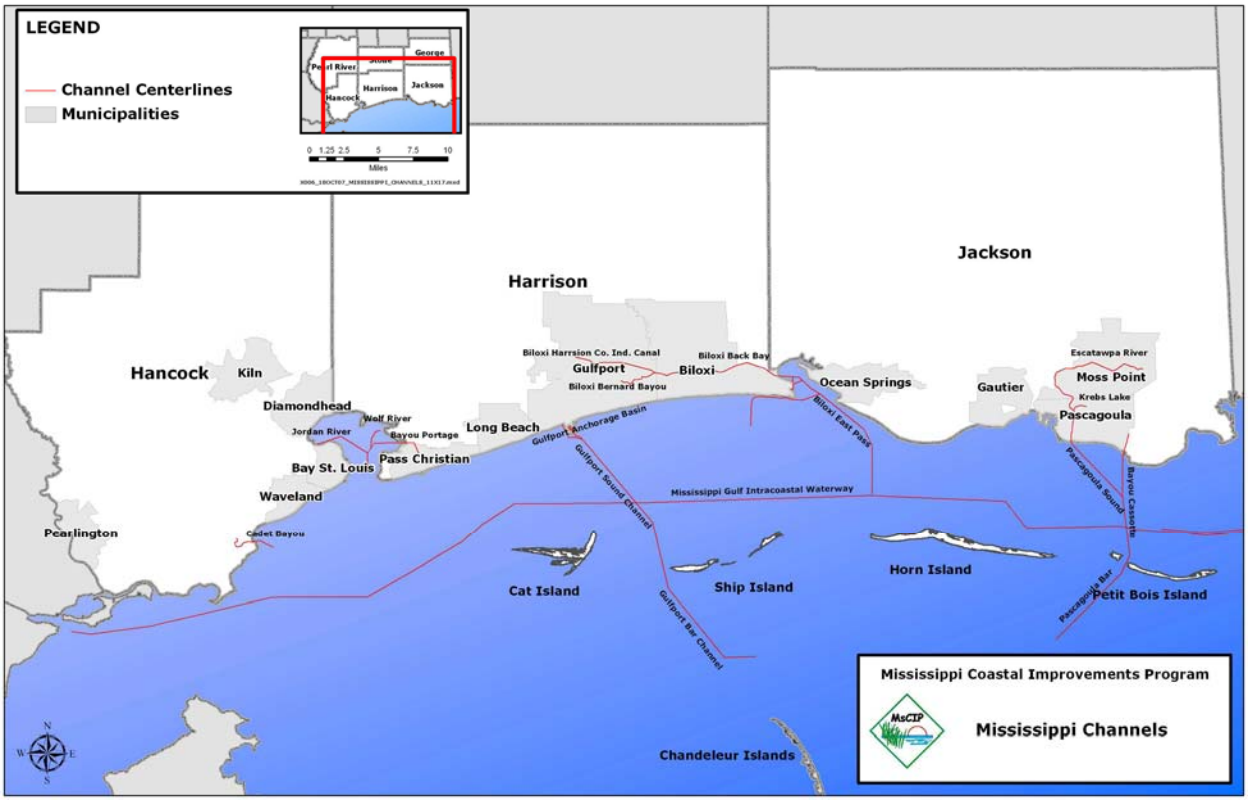

Figure 5.1.1-1. The Mississippi Barrier Islands shown in relationship to the numerous navigation channels near the islands

Immediately following Hurricane Katrina, most of the effort was spent protecting human life and securing structures throughout the impacted areas on the mainland; therefore, few assessments of the vegetation impacts exist, especially on the barrier islands. For the barrier island system, most all of the marsh vegetation recovered several months following Hurricane Katrina. The predominant vegetation that has long-term impacts consists of those pines found in the maritime forests. It is estimated that about 75% of these pine species were killed following the hurricane season of 2005, with most that attributable to Hurricane Katrina. Figure 5.1.1-2 is a photograph taken on Horn Island after Hurricane Katrina that shows the loss to the pine trees. The emergent marsh habitat is thriving so well it actually looks as though hurricanes never past through the barrier island system. The sea oats are still found in small patches due to the reduced dune system. Any option that includes the planting of marsh vegetation will have to consider the current population of nutria that inhabits the islands. These exotic animals from South America can destroy attempts to establish marsh planting and any program should include the control of these rodents.

In 1998, Hurricane George played a role in destroying many of the sand dunes on the islands. Although a relatively small storm, the constant pounding of the waves along the beaches eroded most of the dunes on the southern shores which were the higher elevations on the islands. Along with the destruction of the dunes was the loss of the associated vegetation and habitat. Figure 5.1.1-3 is a photo of the south beach of Horn Island where hurricanes have destroyed the dunes system.

Figure 5.1.1-2. Photo of interior of Horn Island. Note the mature pine trees that were killed from the effects of salt water that covered the island during Hurricane Katrina.

Figure 5.1.1-3. Photo of the south beach at Horn Island. Pre-existing dunes have been destroyed by numerous hurricanes over the last several years.

Prior to Hurricane Katrina, the State of Mississippi was working on a coastal storm protection plan that included restoring the barrier islands to the condition that existed prior to Hurricane Camille. The general assumption was that there would have been less damage along the coast from Hurricane Katrina if the islands had been in this improved condition. This was also included in the Mississippi Governor's Hurricane Katrina Recovery Plan which called for restoring the islands to a pre-Camille footprint. This concept was included in the hurricane protection study as LOD-1.

To determine the effects of the islands in reducing the surge damage to the mainland, a number of storms were selected to model against the chain of islands in a pre-Camille and a post-Katrina configuration. The post-Katrina condition can be considered a baseline condition for the modeling and the pre-Camille condition would be an improved condition. The pre-Camille footprint of the islands was obtained from historical records and an assumption was made as to a top of dune elevation and a typical island width. During the modeling process, the island sizes were held constant and not allowed to be destroyed. It should be noted that some of the islands have migrated and any reconstruction would be to increase their footprint at their present location and not move them back to historical locations. In general, the islands were modeled with a 2000-foot width and with an elevation 20.0 dunes, but may be in a slightly different position. Modeling efforts have concluded that over a wide range of storms, there would be some protection provided to the eastern coast of Mississippi along the Jackson County shoreline if the islands are in the pre-Camille condition. This area is the most protected from the restored islands and this protection may result in only up to a 10% reduction in storm surge. The effect of this protection diminishes rapidly to the west from Jackson County. An important aspect of the islands shown by the modeling is the reduction of the large sea waves as they advance towards the mainland. Reduction in wave height up to several feet is realized by the presence of the islands. Loss of Ship Island would leave a portion of the heavily developed Harrison County shoreline subject to these larger waves.

All of Petit Bois, Horn, and Ship Islands and part of Cat Island are within the boundaries of the Gulf Islands National Seashore under the jurisdiction of the National Park Service. The park boundaries are shown in Figure 5.1.1-4. In most cases, the boundary extends one mile from the shore of the island. Petit Bois and Horn Islands have also been designated as Wilderness Areas by the U.S. Department of the Interior and have a higher degree of protection than the other islands.

The formation of Camille Cut has created problems for the National Park Service due to the location of two historically important sites. Fort Massachusetts is located on the northern shore of West Ship and the French Warehouse is located on the northern shore of East Ship Island. Both of these sites are endangered by on-going erosion of the shoreline with Mississippi Sound. Another site known as the Quarantine Station as already been lost to erosion. These sites are shown in Figure 5.1.1-5. This photo was taken after Hurricane Katrina, but, would be similar to conditions after Hurricane Camille.

Figure 5.1.1-4. Boundaries of the Gulf Islands National Seashore

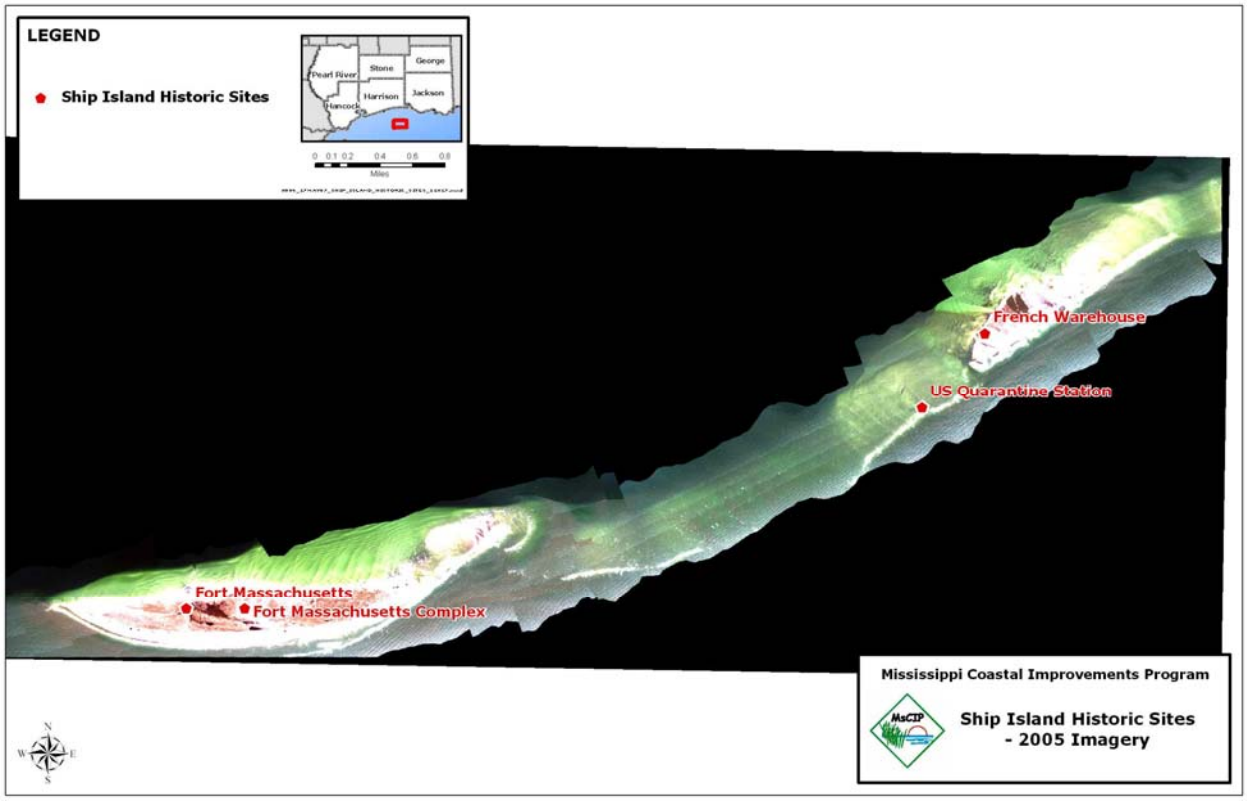

Figure 5.1.1-5. Aerial photo of West and East Ship Island taken in 2005 after Hurricane Katrina showing the locations of listed historical sites separated by Camille Cut

Fort Massachusetts was originally built on the western tip of Ship Island. The westward migration of sand along the southern shore and erosion of the northern shore now has put the fort almost a mile from the western tip of the island, but dangerously close to being in the Sound. Several emergency beach re-nourishments have taken place over the last 35 years to protect the fort from wave action during winter storms. At present, the NPS is again requesting that the Corps place sand along the shore near the fort in conjunction with dredging operations at the Gulfport navigation channel. This emergency placement of sand is being repeated about every five to six years.

The French Warehouse site has not had any sand placement on its shoreline in the past. The erosive process is slower at that location, but now there are concerns from the NPS about the integrity of the site. Unlike the location of the fort, the warehouse site is covered by maritime forest which may be added in slowing the erosion of the shore.

The Corps was asked to visit Fort Massachusetts with the NPS during July, 2007 to look at the present erosion problem and to discuss any possible long-term solutions to the loss of sand along the shoreline. The immediate erosion problem will require re-nourishment of the beach adjacent to the fort similar to the past protection projects. Any type of hardened structural feature as protection for the fort was not desired by the NPS nor was this recommended by the Corps. There was a breakwater placed north of the fort in the past (prior to the barrier islands becoming a National Seashore under the NPS) and seems to be compounding the erosion problems. The problem of a long-term fix may be tied to closing the three mile wide breach known as Camille Pass between West and East Ship Island. Review of historical footprints of the islands indicates that after the breach caused by Hurricane Camille, the westward migration of sand was continuing, but that the sand supply was being depleted before it reached West Ship Island. Aerial photos show the

formation of a sand spit that extends westward from East Ship Island. The volume of sand that is creating this spit is being depleted before it reaches West Ship Island. The photos also show that a deeper channel has formed a pass between the eastern end of West Ship Island and the western end of the spit. It appears that an ebb tidal delta at this pass moves the sand southward where it is removed from any migration along the northern shore of West Ship Island. The sand continues to supply the south beach and extends the western tip of the island in its migration. The loss of the sand from the littoral drift along the northern shore of West ship Island has resulted in erosion of that shoreline. Figure 5.1.1-6 shows an excellent aerial view of this process. Note the boat on the northern side of the pass.

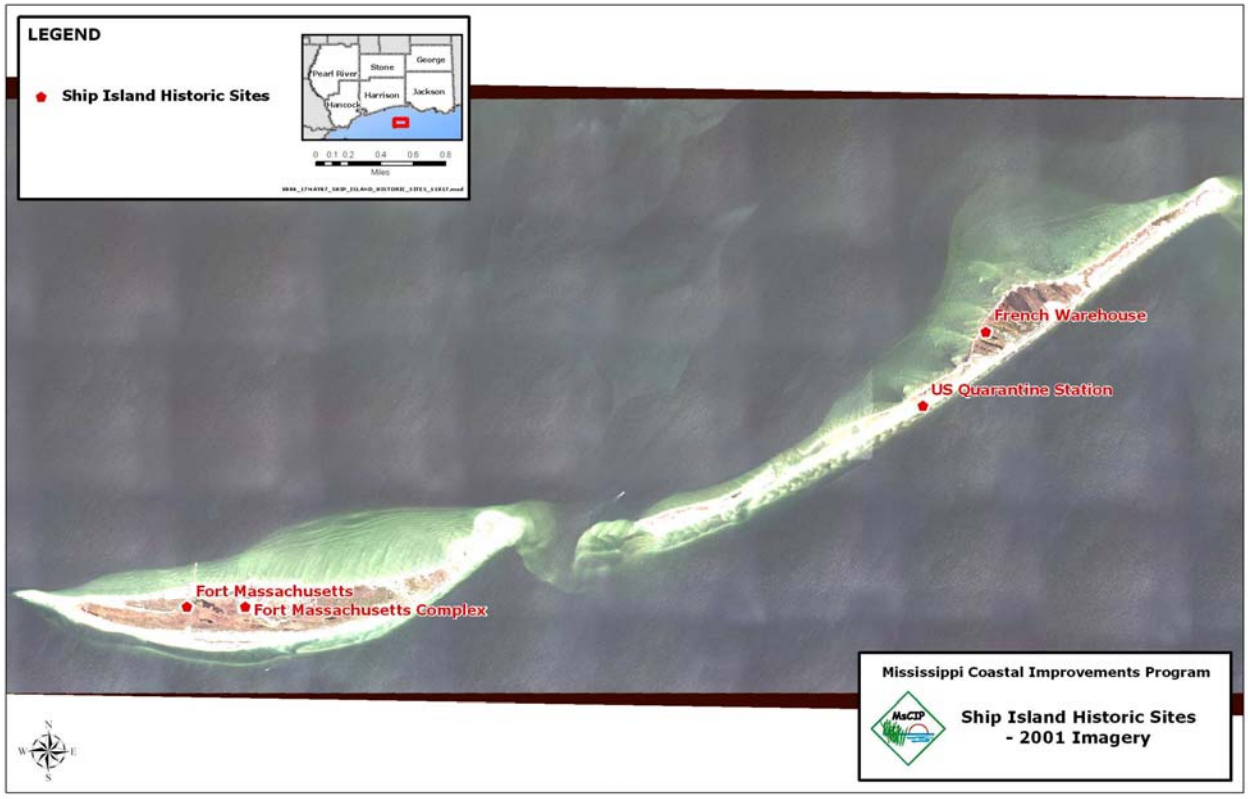

Figure 5.1.1-6. Aerial photo of West and East Ship Island taken in 2001. Note the sand spit extending westward from East Ship Island and the pass between the two islands.

A positive by-product of filling of the Camille Pass would be to provide a longer term solution to the erosion on the northern shores of West Ship Island. This will require modeling to better understand the benefits that are believed to be associated with this plan. The costs will be substantial due to the large quantities of sand high quality sand that will be required to fill the breach. Initial estimates for sand requirements are approximately 13 million cubic yards. The fill would be expected to prevent the continuing loss of sand to West Ship Island, but it is also understood that the islands are a dynamic system, ever changing to nature's forces. Different types of dune vegetation planting would also be included to restore habitat on the newly created land.

5.1.2 Restoration of the Offshore Barrier Islands

5.1.2.1 General

Soon after Hurricane Katrina, it was reported that many residents in Mississippi were of the opinion that if the islands had been in the condition that existed prior to Hurricane Camille, there would have been less damage along the coast from Hurricane Katrina. This initial concept was also included in the Mississippi Governor's Restoration Plan which called for restoring the islands to a pre-Camille footprint. Changes in the footprints are shown in Figures 5.1.2.1-1 through 5.1.2.1-4.

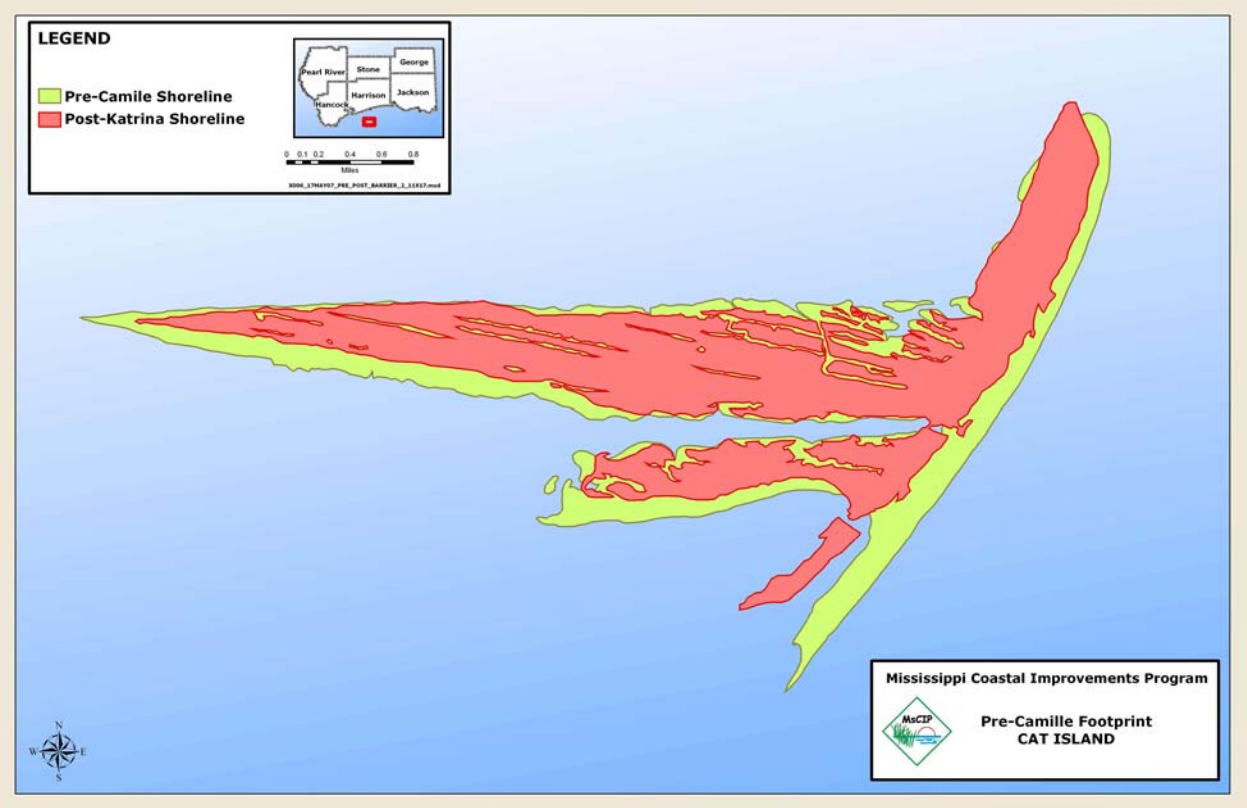

Figure 5.1.2.1-1. Changes in footprint of Cat Island from pre-Camille to post-Katrina

Figure 5.1.2.1-2. Changes in footprint of Ship Island from pre-Camille to post-Katrina

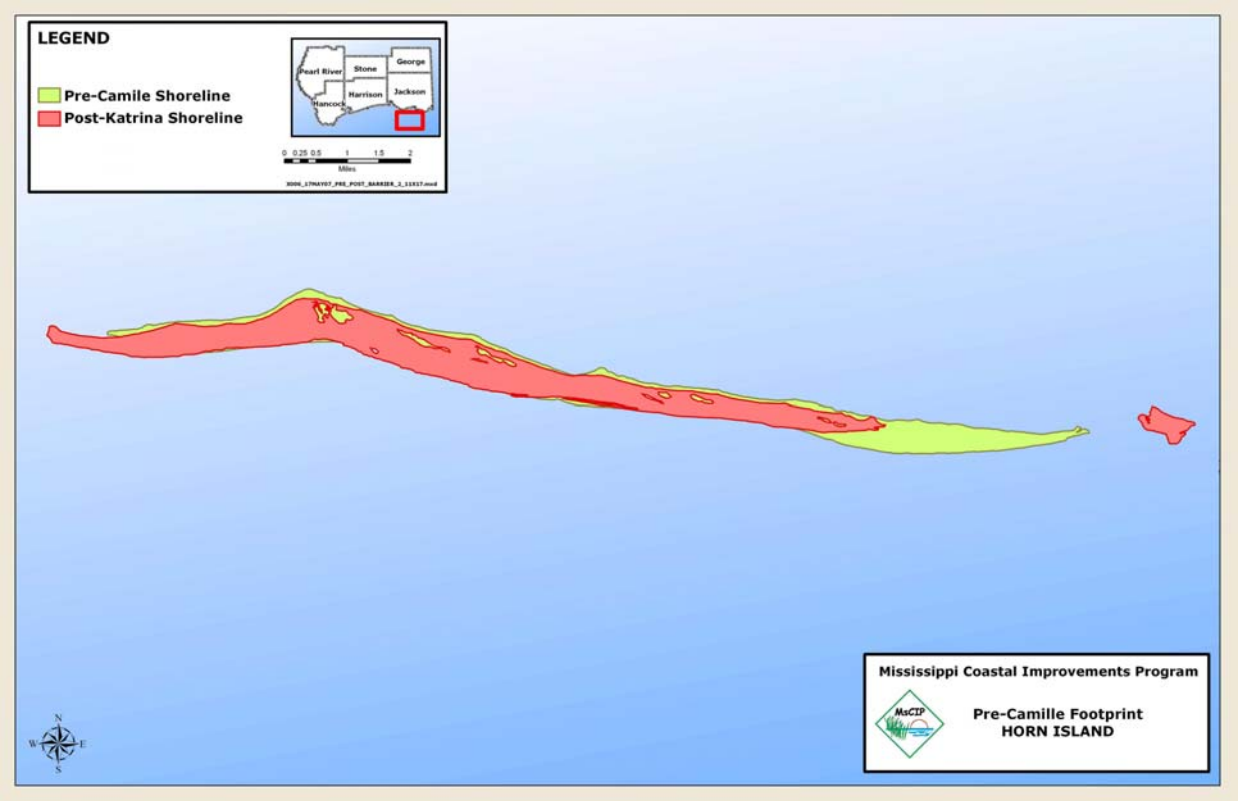

Figure 5.1.2.1-3. Changes in footprint of Horn Island from pre-Camille to post-Katrina

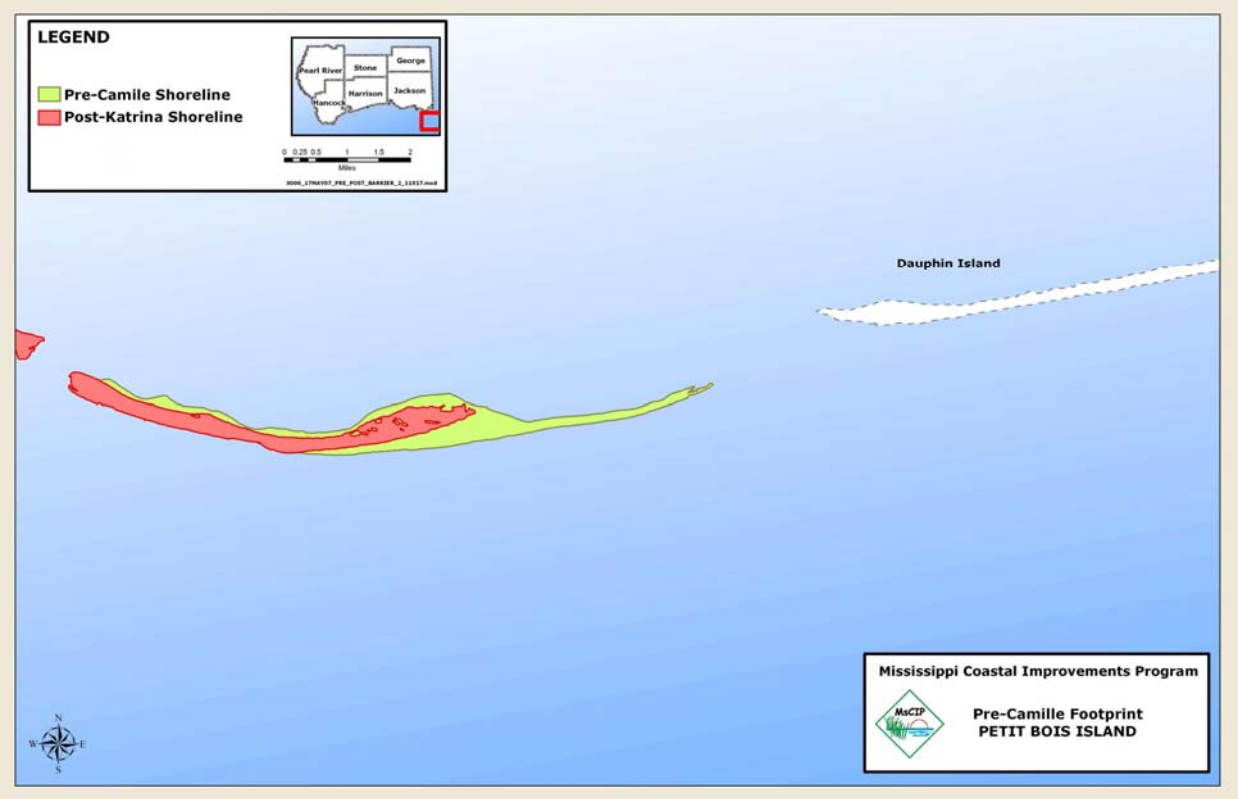

Figure 5.1.2.1-4. Changes in footprint of Petit Bois Island from pre-Camille to post-Katrina

As discussed in the Engineering Appendix, Part 2, a number of storms were selected to model against the chain of islands in a pre-Camille and a post-Katrina configuration. The post-Katrina condition can be considered a baseline condition for the modeling and the pre-Camille condition would be an improved condition. The pre-Camille footprint of the islands (USGS, 2007) was obtained from historical records and an assumption was made as to a top of dune elevation of 20 feet. It should be noted that some of the islands have migrated and any reconstruction would be to increase their footprint at their present location and not move them back to historical locations. This increase in size generally increased their length and maintained their typical width.

Modeling efforts have concluded that over a wide range of storms, there would be some protection provided to the eastern coast of Mississippi along the Jackson County shoreline if the islands are in the pre-Camille condition. This area is the most protected from the restored islands and this protection may result in only up to a 10% reduction in storm surge. As was shown in Figure 5.1.2.1-5, the effect of this protection diminishes rapidly to the west from Jackson County. With the consideration that these islands are within the National Park Service and that Petit Bois and Horn Islands are designated Wilderness Areas, any extensive restorations to these islands may not be feasible based on the limited reduction in storm surge.

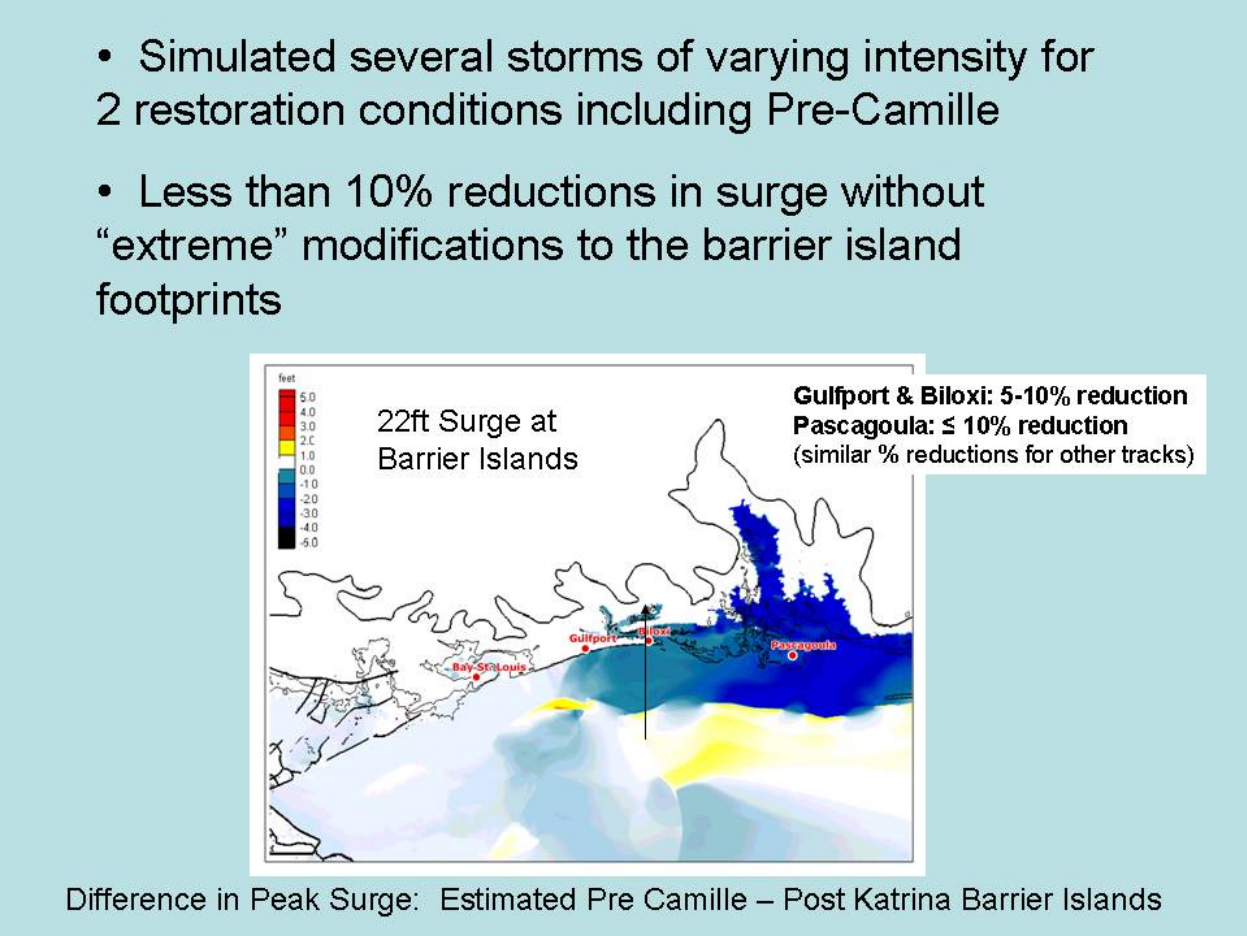

Figure 5.1.2.1-5 Difference in Peak Surge between pre-Camille and post-Katrina barrier islands

Another consideration to help restore the islands is to supplement the sand into the littoral system. This could be accomplished by adding sand in specific locations based on sediment transport modeling. This sand would not be put on the islands, but in areas between the islands where the currents that make up the littoral drift zone could transport the sand to the islands where the natural process of island building could take place. There, waves and wind could cause accretion on the islands. This may mitigate the loss of land mass at the islands that has been occurring since Hurricane Camille. The source of these sands may be from inland sources or from offshore borrow areas. This would not directly affect the present-day islands and would help mitigate any effects of dredging the ship channels that pass through the chain of islands where sand may have been lost from the system.

A positive affect that the islands have is to provide a natural off-shore breakwater for the large sea waves that are generated from hurricanes. For this to occur, the islands only need to be a low stretch of sand or even a shallow sandbar. The presence of the islands and the relatively shallow water of the Mississippi Sound between the islands and the mainland prevent the sea waves from maintaining their considerable size as they move towards the mainland. Sea waves, often reported at heights of 40 feet and higher in large storms, would break as they approach the chain of islands. The open water between the islands and the mainland, generally ten miles or more, would have enough fetch for waves to regenerate, but at a much lower height do to the shallower water. The generally accepted relationship between water depth and wave height is that the wave can sustain itself at a height that is one half the depth of the water.

An environmental impact of the islands continuing to diminish in size is to allow salinity increases in the Mississippi Sound. Under current conditions, the islands provide a boundary condition between the sea water salinity of the open Gulf of Mexico and the brackish water found in the Sound. Loss of the islands would allow the salinity in the Sound to increase and result in a change of the ecological habitats that exist now. This would impact shellfish and other forms of marine life. This occurred at the Chandeleur Islands near the Mississippi barrier islands when almost the entire island structure was eroded away by Hurricane Katrina (see Figure 5.1.2.1-6). Mississippi Sound is classified as a 'bar-built' estuary as opposed to 'drowned river valley' (like Mobile Bay). The physics of bar-built estuaries is very different from others and you would expect to see broad zones of 'salinities' with the estuary which respond greatly to both river flow and wind conditions. Should the 'bars' go away then the estuary is totally lost because in general an estuary is considered part of the coast as opposed to forming the coast.

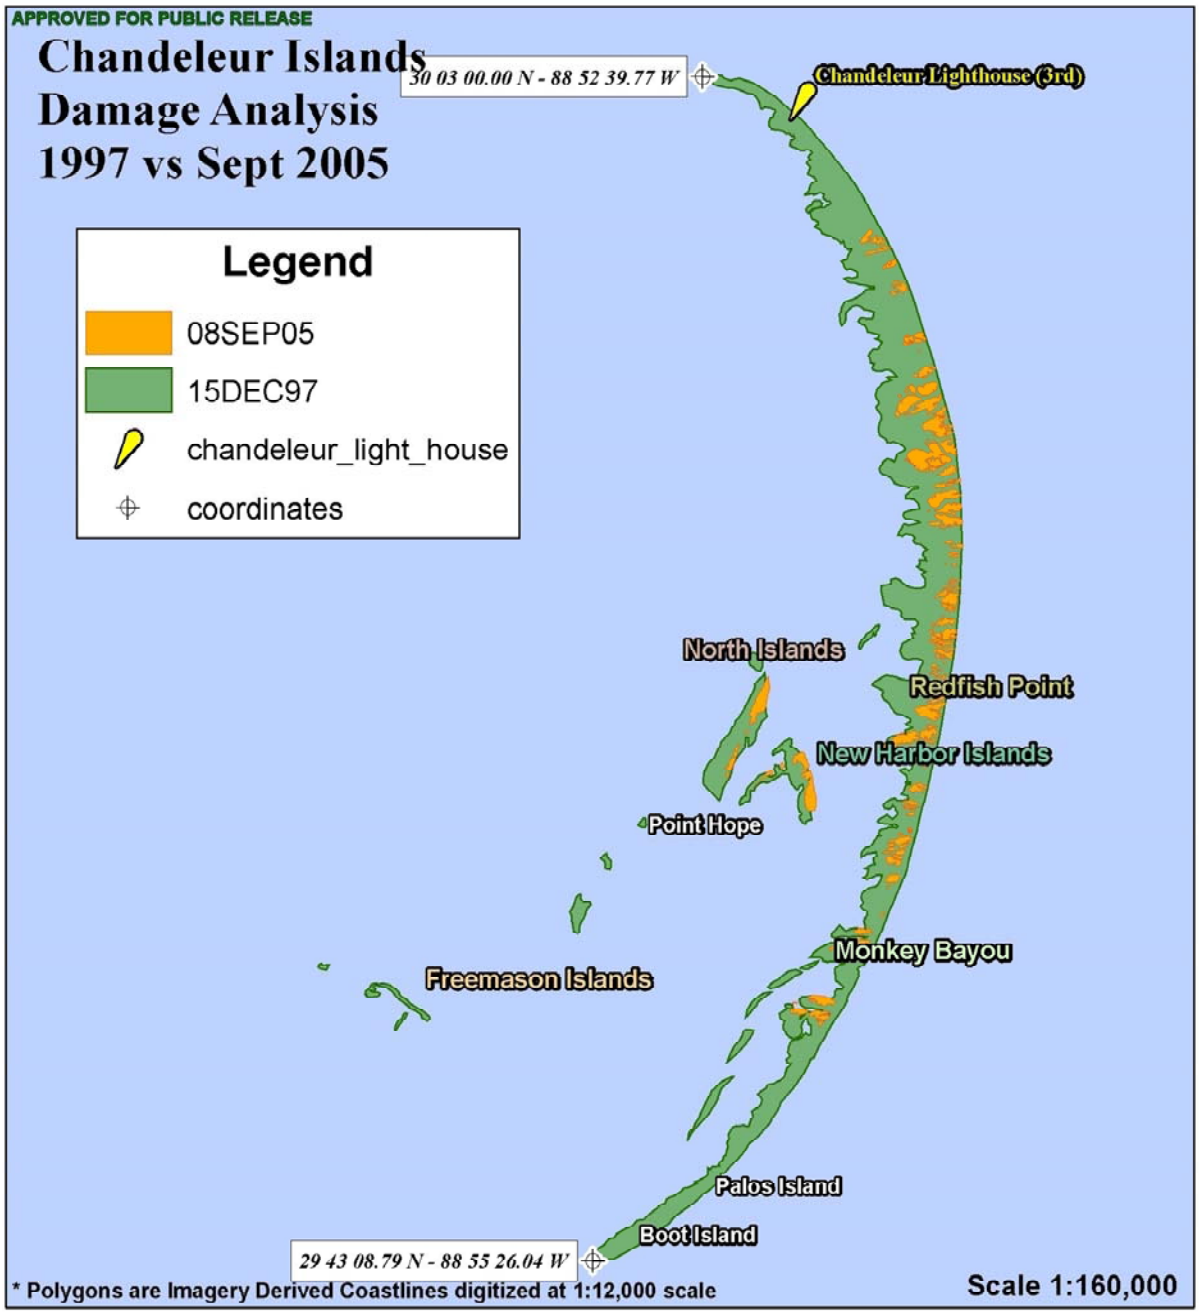

Figure 5.1.2.1-6. Loss of land mass from storm erosion at the Chandeleur Islands, 1997 to 2005. (US Navy)

One restoration option for the barrier islands would be to re-establish the vegetation that was destroyed by Hurricane Katrina. This option could involve environmental restoration of the existing islands through adding sand dunes on the beaches along with planted vegetation, planting of marshes and maritime forests, and planting sea grasses in the near-shore areas of the islands. This plan would not involve adding any land mass to the islands other than the possibility of adding to the dune system. The addition of vegetation from sea oats up to trees would aid in reducing erosion of the sand from wind thus helping in maintaining the stability of the islands. The vegetation would also aid in preventing erosion by water in the event that the islands gets overtopped by storm surge in a large hurricane. Sources of this sand could be from the beach area behind the dunes or from

sources off the island. Historically, large areas of sea grass existed north of the islands. Much of this sea grass is now gone and the loss of these areas have been mapped. Replanting the grasses and other vegetation will aid in establishing valuable habitat that was lost from the ecological system. Figure 5.1.2.1-7 shows the extent of vegetation on Horn Island prior to Hurricane Katrina.

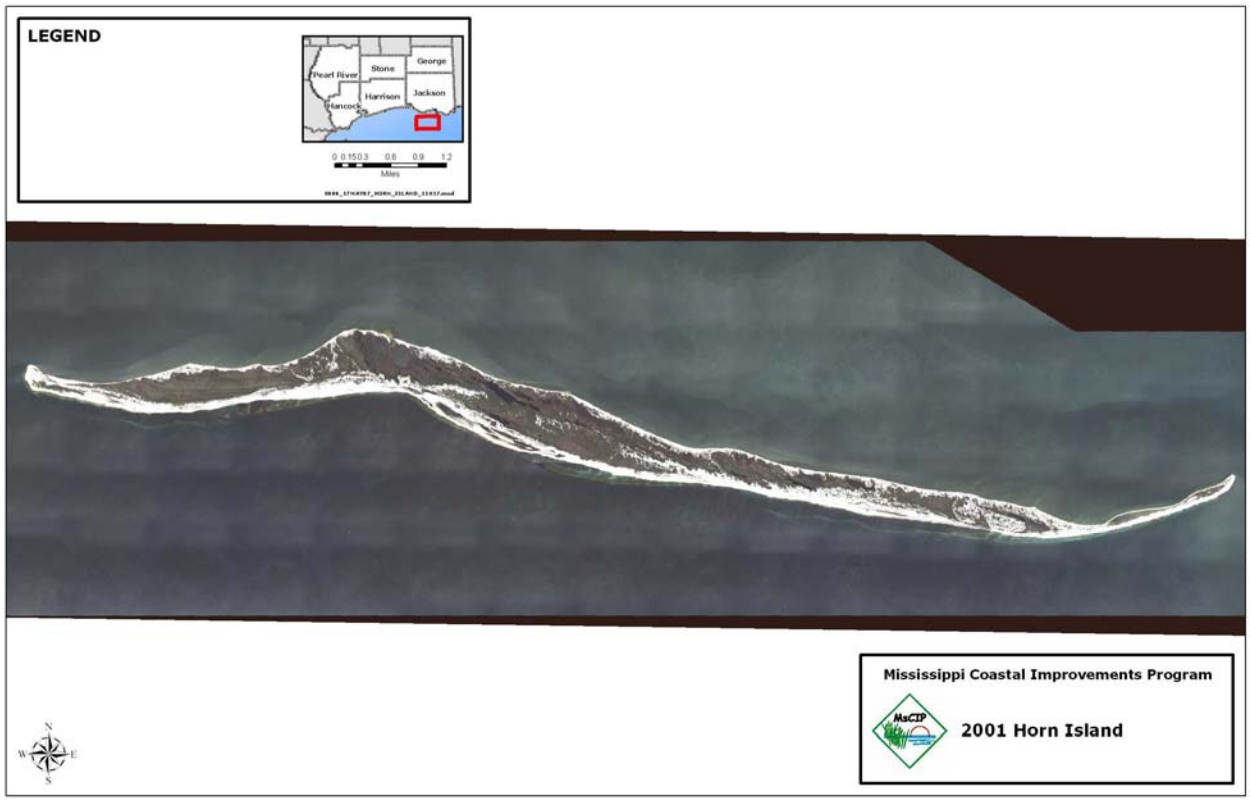

Figure 5.1.2.1-7. Aerial photo of Horn Island. The darker areas are vegetation consisting of maritime forest and marsh grasses.

As was mentioned at the end of Section 5.1.1 and will be discussed in more detail in Chapter 7 of this Appendix, an additional restoration option was added that will fill and close Camille Cut between West and East Ship Island. In addition to providing some storm damage reduction, this option will provide some protection to two historical sites on West and East Ship Island, respectively. This degree of protection is desired by the NPS and meets the goal of storm damage reduction and helping maintain the integrity of the Mississippi Sound estuary. This option will require additional study to model the desired results of slowing erosion near the two sites. These proposals have been incorporated into LOD-1 under Options C and G by adding sand into the littoral zone and closing the breach between West and East Ship island. A working paper that documents the NPS position on the barrier islands (NPS, Sept. 2007) along with other cooperating agencies is included in Chapter 6 of this Appendix. An important result of the NPS agreement was that any work that involved direct placement of sand into Camille Cut would be a one-time event without additional O&M sand placement. In accordance with 2006 NPS Management Policies (see Chapter 2, the NPS Vision Statement Section III), the NPS has concluded that this one-time placement of sand would mostly directly counteract the long-term reduction in sand supply which has resulted in Ship Island being diminished to the point where it may have lost the ability to restore and maintain itself as in the historical past. Natural re-building and maintenance of the barrier islands in the long-term would then be supported by the continuing placement of sand back into the littoral zone during future maintenance dredging of navigation channels under revised Regional Sediment Mamagement

Practices. Two important areas where this will be employed is the Pascagoula Navigation Channel and the Gulfport Navigation Channel.

5.1.3 Location

The barrier islands of Mississippi are located 10 to 15 miles south of the mainland as shown in Figure 5.1.1-1. Currently, there are five islands in the chain that extends for 45 miles west from a point south of the Alabama – Mississippi state line along the coast. Currently, Ship Island exists as two islands separated by Camille Cut. It was breached during Hurricane Camille in 1969 and remains today as West and East Ship Island. Two maintained navigation channels pass through the chain of islands. The Gulfport channel passes near the west end of West Ship Island and the Pascagoula channel passes near the end of Petit Bois Island. The present day location of the channels prevents any further westward migration of either island.

5.1.4 Existing Conditions

As is typical of most barrier island systems, the Mississippi islands are an ever-changing and dynamic landscape. Data shows that the islands have lost approximately 20 to 25 percent of their land mass since pre-Camille times. The islands have been heavily influenced by the various hurricanes including even the lower intensity ones. Hurricane George, in 1998, even though a small hurricane, proved to be devastating to the islands due heavy erosion from waves. Many of the higher dunes systems on the islands were destroyed and much of the elevation the islands once had is gone. Most of the islands are now very susceptible to over-wash during storms. Another result of being submerged during Hurricane Katrina was the loss of much of the maritime pine forest that existed on the islands. The trees, mostly now dead from the salt water submergence, played a major role in preventing erosion both from wind and any surges against the islands.

The westernmost island, Cat Island, has a similar origin from the other islands in the chain, but isolated from the littoral current by a historical birds-foot delta from the Mississippi River that cut off the path of the historical littoral zone. A change in wave climate has formed a T-shaped configuration. Sorting of the sediments has created a beach on the east facing portion of the island. Results of the sediment budget completed as part of this study indicates that little or no sand in being added to Cat Island from the littoral drift system that supplies sand to the other islands in the chain. The remainder of the islands have a westward drift that is more pronounced from the eastern-most Petit Bois Island and decreasing respectively to the west to West Ship Island.

5.1.5 Coastal and Hydraulic Data

The barrier islands protecting the Mississippi Sound experience a low energy wave climate, with average significant wave height at National Data Buoy Center (NDBC) Buoy 42007 (22 nautical miles south-southeast of Biloxi, in 45 ft depth) averaging 2.0 and 1.3 feet in the winter and summer months, with associated average peak wave periods of 4.0 to 3.5 s, respectively. Wave transformation modeling by Cipriani and Stone (2001) indicated that breaking wave heights on the barrier islands range from 1.0 to 2.0 feet. Waves in the Mississippi Sound are fetch and depth-limited. The Coastal Studies Institute's Wave-Current Surge Information System (WAVCIS) gage CSI-13 located at Ship Island Pass (23 foot depth) from June 1998 through July 2005 measured an average significant wave height of 0.3 feet and associated average wave period of 2.5 sec.

Tides in the Mississippi Sound are diurnal, with a tidal range of 1.5 and 2.8 feet for the mean and spring tides at Biloxi, Mississippi, respectively. However, the relatively shallow and large area of the Mississippi Sound create strong currents in the tidal passes between the barrier islands, ranging from 1.6 to 3.3 feet/sec and 6.0 to 11.5 feet/sec on flood and ebb tides, respectively (Foxworth et al. 1962). In the winter months, winds from the same direction and of a sufficient magnitude are capable

of lowering water surface elevations in the bays and nearshore from 3.6 to 2.0 feet (U.S. Army Corps of Engineers Mobile District 1984).

For the Gulf barrier island beaches, net longshore sediment transport is from east to west, although local reversals in the net transport occur adjacent to the tidal passes. The primary sources of sediment are longshore sediment transport from east to west, and, potentially, the offshore shelf (Otvos 1979, Cipriani and Stone 2001). Cipriani and Stone (2001) discussed that a well-defined cellular structure exists for each barrier island in which, over historic times, little sand transfer exists between islands. However, dredging records at Horn Island and Ship Island Passes (called Pascagoula Bar Channel and Gulfport Bar Channel, respectively) suggest that infilling of sand from adjacent barrier islands occurs, indicating the potential for transport of sand between islands. Eastern Dauphin Island, with a Pleistocene core, is more stable than the other barriers although eastern Dauphin Island has been eroding in response to the dominant westerly-directed transport. Based on grain size analysis, Cipriani and Stone (2001) inferred that offshore sources may provide some sediment to central Petit Bois Island. The Mississippi Sound barrier islands range from very well vegetated, with maritime forests on east Dauphin Island, to low elevation barriers that are overwashed and breached during hurricanes. Long-term relative sea level rise for Dauphin Island, Alabama from 1966 to 1997 was 0.12 inch/year +/- 0.02 inch/year.

5.1.6 Engineering Options

5.1.6.1 General

Seven separate options were included in the Engineering Appendix. All were based on some variation of direct sand placement and shaping, establishing vegetation and littoral zone sand additions. Each of the LOD-1 Options, A through G, have a brief description below. Full descriptions of each option can be found in the Engineering Appendix.

5.1.6.2 LOD-1, Option A

This option will only include new land mass that is being added to the islands by using sand dredged and transported from an off-shore location. The shaping of the sand into beaches, dunes and marsh areas will not affect the existing islands other than that narrow strip of land that will form the boundary between the existing island and the new land mass. This option can be used in combination with other options under this line of defense should it be desired to restore habitat on the existing islands.

5.1.6.3 LOD-1, Option B

Another consideration to help restore the islands is to supplement the sand in the littoral system. This could be accomplished by adding sand in specific locations based on sediment transport modeling. This would allow the littoral currents to move the sand onto the islands where the natural process of island building could take place. This would not directly affect the present-day islands and would help mitigate any effects of dredging the ship channels that pass through the chain of islands where sand may have been lost from the system. This option would obtain the sand from the beneficial use of dredged material from an inland river source.

5.1.6.4 LOD-1, Option C

Another consideration similar to Option B is to help restore the islands is to supplement the sand in the littoral system at Petit Bois and Ship Island. Sand will be obtained from offshore sources (same as Option A) for Ship Island and from inland river sources (same as Option B) for Petit Bois Island

based on sand quality and compatibility requirements. Like Option B, this could be accomplished by adding sand in specific locations based on sediment transport modeling.

5.1.6.5 LOD-1, Option D

This option would involve environmental restoration of the existing islands. This would consist of shaping existing beach sand into low, 2-foot high dunes on the beaches. This would be along with planted vegetation on the dunes and planting of maritime forests in the inland's interior where they were mostly destroyed by Hurricane Katrina.

5.1.6.6 LOD-1, Option E

This option would involve environmental restoration of the islands consisting of placing and shaping sand into 6-foot dunes on the beaches with planted vegetation and planting of maritime forests on the existing islands where they were mostly destroyed by Hurricane Katrina. The sand required to construct a dune of this size would be more than could be removed from the existing beach berm and would come from the same offshore borrow area as the sand used in Option A. Placement of the sand would require moving the sand from a hopper dredge to a staging area on the beach, then moving the sand to the area of placement along the beach.

5.1.6.7 LOD-1, Option F

This option would involve environmental restoration of the sea grass beds that have historically existed on the north side of the islands in the Mississippi Sound. Despite continual changes that occur, the barrier islands remain to buffer the mainland from storms and provide habitat for the rich, diverse wildlife residing within the area.

5.1.6.8 LOD-1, Option G

The pre-Camille footprint of Ship Island was obtained from historical records. This data showed the area that was breached during Hurricane Camille forming two separate islands. West and East Ship Island has two major historic sites that are in danger from the continuing erosion of the barrier islands. Current studies by the Corps indicate that restoring the two islands to a single island, pre-Camille condition may prevent the rapid erosion of the beaches that is now occurring. Estimates indicated that the restoration of Ship Island to a single land mass off the Mississippi coast will involve approximately 8 million cubic yards of sand. As happened during Hurricane Camille, the breach was opened during Hurricane Katrina leaving two islands with approximately three miles of open water between the remaining portions. To mitigate this problem, the breach could be filled as single operation up to an elevation that would help withstand over-wash until planted vegetation could be come established and promote stable dunes.

CHAPTER 6 MULTI-AGENCY MISSISSIPPI BARRIER ISLAND RESTORATION RECOMMENDATION

6.1 General

To complete its recommendation for the barrier islands the National Park Service met and coordinated with many different agencies including the Corps of Engineers, United States Geological Survey, National Marine Fisheries Service, Environmental Protection Agency, National Oceanic and Atmospheric Administration, US Fish and Wildlife Service, and Mississippi Department of Marine Resources.

6.2 Introduction

The Mississippi barrier islands consisting of Petit Bois, Horn, East and West Ship Islands, and portions of Cat Island are located within Gulf Islands National Seashore (Seashore), a park unit managed by the National Park Service (NPS). The NPS also administers the 401-acre Davis Bayou area on the mainland near Ocean Springs, Mississippi. The Seashore's purpose is to preserve, protect, and interpret its Gulf Coast barrier island and bayou ecosystem and its system of historic coastal defense fortifications, while providing for public use and enjoyment.

The Mississippi barrier islands are dynamic coastal landforms that act as the first line of defense between the ocean and mainland coast, and bear the full impact of atmospheric and oceanic energy (Figure 6.5-1). In addition, the barrier islands contribute to the maintenance of the highly productive Mississippi Sound ecosystem. Hurricanes, variations in sediment supply, and relative sea level rise drive changes in island location and morphology, and effective barrier island management requires adaptation to their dynamics.

The Mississippi barrier islands have experienced substantial changes in shoreline position and island landmass since the mid-1800s. Lateral island migration (erosion along the eastern end of the islands and sand deposition to the west) has occurred, driven by dominant east-to-west longshore sand transport. The long-term and accelerating erosion and land loss experienced by the barrier islands is of major concern to the NPS.

Factors contributing to erosion of the barrier islands include storms, relative sea level rise, and anthropogenic activities, including dredging of sand from the Horn Island Pass Outer Bar Channel (Figure 6.5-1). Such activities have likely resulted in a progressive reduction in sand supply downdrift to Horn Island and Ship Island (now East and West Ship Island). Significant storm events and a reduction in sand supply has contributed to substantial upland land area losses between 1847 and 2005 ranging from 24% at Horn Island to 64% at the Ship Islands. In addition, Petit Bois Island, which is located east (updrift) of Horn Island Pass, has experienced a 56% reduction in upland land area between 1847 and 2005 (Morton, 2007).

The regional shortage of littoral sand for barrier island maintenance is most profound at the Ship Islands, located at the terminus of the sediment transport system along the Mississippi barrier islands. Cat Island, located west of the Ship Islands, is not part of the sand-sharing system that comprises the other barrier islands, and is considered to be a separate entity (Rosati et al., 2007). Consequently, the Ship Islands' vulnerability to breaching has progressively increased with time.

Because of the island's diminished state, it may now have lost the ability to restore and maintain itself as in the historical past (Morton, 2007), placing the island's cultural resources, historic Fort Massachusetts and the French Warehouse archeological site, at great risk (Figure 6.5-2).

Given the altered state of natural resource processes due in part to human-caused intervention, as well as the resulting threats to cultural resources, the NPS in collaboration with other agencies (USACE, USGS, NMFS, EPA, NOAA, USFWS, and MDMR) has concluded that specific emergency actions and long-term restoration of the sediment transport system and budget are crucial and necessary for preserving and protecting the Mississippi barrier islands' natural and cultural resources. This Mississippi barrier island restoration recommendation represents the results of extensive interagency consultation and collaboration.

6.3 Background

6.3.1 NPS Management of Mississippi Barrier Islands

Gulf Islands National Seashore includes outstanding natural, cultural, and recreational resources along the northern Gulf of Mexico coasts of Florida and Mississippi. These resources include several coastal defense forts spanning more than two centuries of military activity, archeological values, pristine examples of intact coastal barrier islands, salt marshes, bayous and submerged seagrass beds, complex terrestrial communities, emerald green water, and white sand beaches. The barrier islands within the Seashore are nationally significant for several reasons. Specifically, these islands:

- contain one of the most complete collections of publicly accessible seacoast defense structures in the United States, representing a continuum of development from early French and Spanish exploration and colonization through World War II;
- provide the public with recreational opportunities on natural and scenic island, beach, dune and water areas which possess the rare combination of remaining undeveloped and in a wilderness state, yet are located in close proximity to major population centers;
- provide habitat for several endangered species in diverse ecosystems, stop-over habitat for migratory birds, and critical nursery habitat for marine flora and fauna, and serve as an enclave for complex terrestrial and aquatic plant and animal communities that characterize the northern Gulf Coast, and fully illustrate the natural processes which shape these unique areas;
- contain land and marine archeological resources which represent a continuum of human occupation in a coastal environment and are important in enhancing the knowledge of the past including interactions between the earliest settlers and original inhabitants of this area of the Gulf Coast; and
- provide a benchmark to compare conditions in developed areas of the Gulf Coast to natural areas within the park.

The NPS's vision for management of the Mississippi barrier islands (Chapter 2) includes the preservation of natural biological and geological marine and terrestrial conditions and processes, and the preservation of cultural resources, consistent with peer-reviewed and documented scientific study. Horn and Petit Bois Islands, which are designated wilderness areas, receive an even higher level of protection. In these areas, the NPS vision and management focuses on providing park visitors with an undisturbed environment, a pristine and unencumbered viewshed, an atmosphere of solitude, an opportunity for primitive, unconfined recreation, and negligible evidence of resource impairment. The NPS implements this vision by controlling nonconforming uses, preventing

unnecessary or undue reduction of wilderness values, and applying the “minimum requirement” concept of the 1964 Wilderness Act to all proposed projects involving these islands.

Based on federal statutes such as the National Park Service Organic Act and the Seashore’s enabling legislation, NPS Management Policies, and management plans, the NPS is mandated to preserve and protect the natural conditions and processes affecting the barrier islands, and to preserve the significant cultural resources existing on the islands. In addition, the Seashore’s enabling statute directs that beach erosion control measures and spoil deposition activities in the park undertaken by the U.S. Army Corps of Engineers must be carried out in a manner that is acceptable to the NPS and consistent with the park’s purposes (16 U.S.C. § 459h-5). NPS decision-making must also integrate the results of scientific study (16 U.S.C. § 5936).

6.3.2 Impacts to Mississippi Barrier Islands and Processes

Net longshore sand transport is from east to west along the Mississippi barrier islands, although local reversals in the net transport occur adjacent to the tidal passes. Based on analysis of historical shoreline and bathymetry data, Ship Island is the terminus to the longshore sand transport system in this region. Modern Cat Island beaches, located west of Ship Island, appear to be affected by littoral processes not directly related to those of the islands to the east. Thus, the regional shortage of littoral sand for barrier island maintenance is best observed at Ship Island (Rosati et al., 2007).

Between the late 1840s and 2005, all of the Mississippi barrier islands managed by the NPS have eroded and migrated appreciably. Petit Bois Island lost about 56% of its surface area, Horn Island lost approximately 24%, East and West Ship Islands have cumulatively lost about 64%, and Cat Island lost approximately 26% (Morton, 2007). Furthermore, island erosion rates have increased more than three fold between 1847 and 2000/2002. For example, Ship Island lost about 0.9 hectares/year between 1848 and 1917, increasing to approximately 2.5 hectares/year between 1917 and 2000 (Rosati, et al., 2007). Additionally, between 2000 and 2005, a period of significant storm events, the Ship Islands lost about 22 hectares/year (Morton, 2007). In 1847, Ship Island had a surface area of approximately 603 hectares (Rosati, et al., 2007), but by 2005 the total surface area for East and West Ship Islands had decreased to about 216 hectares (Morton, 2007).

The principle causes of Mississippi barrier island erosion and land loss are frequent intense storms, a relative rise in sea level, and a deficit in the sediment budget. Of these causes, the one that experienced the greatest change over the last 100+ years is the reduction in sand supply related to dredging of navigation channels through the outer bars of the tidal inlets near the islands (Morton 2007). According to Rosati et al. (2007), maintenance dredging operations conducted between 1897 and 1948 in the Horn Island Pass Outer Bar Channel removed sediment at a rate of approximately 34000 cubic yards per year (cy/yr). After the channel was modified to 38-feet deep by local interests in 1949 at their expense, maintenance dredging quantities continued to increase as authorized channel depths increased. Maintenance dredging rates increased to161,104 cy/yr in 1949-1965, increased again to 515,320 cy/yr in 1965-1993, and decreased to a rate of 245,483 cy/yr in 1993-2005.

Therefore, between 1909 and 2005, a total of approximately 22 million cubic yards of sand were removed from the Horn Island Pass Outer Bar Channel by maintenance dredging (Rosati et al., 2007). Much of the sand dredged from the outer bar channel during maintenance dredging operations likely originated from littoral zone transport east of the channel. Offshore disposal of sand dredged during channel maintenance operations conducted in the past may have removed such sand from the barrier island sediment budget downdrift of the channel. However, a detailed analysis of the dredging/placement records and the resulting impact on the barrier island sediment budget has yet to be determined. Additional investigations into past dredged material placement quantities and locations relative to the regional barrier island sediment budget need to be conducted.

Ship Island experienced breaching by hurricanes in 1852, 1916, 1947, and 1969 (Hurricane Camille). However, pre-Camille breaches eventually shoaled and the narrow, low-profile barrier beach reformed through natural processes. Since 1969, Ship Island has been separated into two islands (East and West Ship) by "Camille Cut." Between 1969 and 2002, the average width of Camille Cut between the Ship Islands was approximately one mile. However, the breach widened to about three miles following the passage of Hurricane Georges in 1998, creating a shallow subaqueous shoal across the eastern one-mile of the breach area. Although precise depth measurements are not yet available, water depth across most of the breach area is estimated at 1 to 5 feet, and the channel that has formed adjacent to the east end of West Ship Island is about nine-feet deep (Figure 6.5-2).

Recent scientific reports present concerns regarding the existing condition of the Ship Islands and their ability to restore themselves to a single island once again based on current trends (i.e., accrete enough sand to shoal, closing the Camille Cut breach and channel, and redeveloping the narrow, low-profile barrier beach). Morton (2007) states "the historical record for Ship Island indicates that its vulnerability to breaching progressively increased with time and that because of its diminished state, the Camille Cut inlet will not shoal and East and West segments will not become reattached as in the past." Rosati et al. (2007) also notes "disintegration of this barrier island (Ship Island), especially since Hurricane Katrina in 2005."

Beach erosion along the Mississippi Sound (Sound) shoreline of East and West Ship Islands currently threatens the French Warehouse archeological site and historic Fort Massachusetts (constructed between 1859 and 1866), respectively. Relatively small-scale beach renourishment projects with sand volumes ranging from 44,346 to 160,566 cubic meters were authorized in 1974, 1980, 1984, 1991 and 2002 to advance the north shoreline on West Ship Island to protect Fort Massachusetts. Observations indicate that Camille Cut may be exacerbating erosion along the northeast shoreline of West Ship Island, and it may be interrupting sediment transport downdrift toward Fort Massachusetts.

The consequences of continued erosion of the Mississippi barrier islands affect not just the islands themselves, but the physical, chemical and biological integrity of the Sound and the Mississippi mainland coast. In the broader regional sense, the physical integrity of these barrier islands may provide the Sound and coastal counties some degree of protection from the energy generated by tropical storms and hurricanes. Ocean surge generated by hurricanes has been modeled with and without these islands for a variety of storm tracts, intensities and forward speed. As modeled, ocean surge protection provided by these islands is estimated between two (2) and four (4) feet, with a general tendency of greater protection toward the eastern area of the Mississippi mainland coast (Ty Wamsley, personal communication, Sept. 18, 2007).

Wave height modeling for a variety of storm tracts, intensities and forward speed also shows that the physical presence of the barrier islands may reduce expected wave height at the Mississippi mainland shoreline by four (4) to six (6) feet. Again, the barrier islands afford a greater degree of protection relative to wave height reduction toward the eastern area of the Mississippi mainland coast (Ty Wamsley, personal communication, Sept. 18, 2007). Furthermore, combining predicted surge and wave height modeling results shows that total loss of the Mississippi barrier islands may increase the elevation of adverse impacts on mainland coastal areas on the order of an additional six (6) to ten (10) feet.

The loss of any one barrier island would result in a more localized coastal impact. Localized increases in surge, wave height and current speeds would likely occur due north and west of a barrier island lost from the system. Additional modeling is necessary to determine the potential impacts to the mainland coastal area if the Ship Islands continued to erode to a shallow sand shoal.

Water chemistry within the Sound would be expected to change as well with the physical loss of any one or more of the barrier islands. Specifically, salinity gradients may increase in the Sound north of any area of greater exposure to Gulf of Mexico waters resulting from continued erosion and loss of the barrier islands, or the creation of additional water exchange pathways (passes, cuts, etc.). Baseline salinity modeling completed by USACE Engineer Research and Development Center demonstrates this potential gradient increase. Salinity gradient increases resulting from new or expanded passes or cuts would result in greater penetration of oyster drills into the Sound. The expansion of salinity gradients and related penetration of oyster drills increases potential adverse affects on Sound oyster beds.

Other biological communities, such as submergent and emergent grass beds, marshes, scrub/shrub and forest vegetation communities could be adversely affected by the continued erosion and land loss of the barrier islands. Predicted higher storm surge, waves and energy would likely shift these vegetation communities landward over time. Disruptions of these existing vegetation communities exposes highly erodeable soils, and when subjected to high energy, may increase water turbidity and decrease light penetration, reducing submergent vegetation and depositing sediment on existing oyster beds. Emergent vegetation in the Sound and along the coastline provides protection from storm surge and wave action. These components also provide significant benefits for aquatic and aquatic-dependent faunal species of this area. Food, cover, spawning and nursery sites for estuarine and marine organisms require some or all of these submergent and emergent vegetative communities during their life cycles. Coastal areas that have significant emergent marshes, scrub/shrub and forested vegetative communities in the tidal zone have significantly less wind and storm surge damage than coastal areas adjacent to open water.

Continued erosion and loss of the Mississippi barrier islands within Gulf Islands National Seashore could result in significant adverse consequences not only to the natural and cultural resources managed by the NPS, but also to the overall health of the Mississippi Sound ecosystem and mainland coastal communities. Under a no action scenario, barrier island land loss will continue to increase. At the current rate of erosion and land loss on East and West Ship Islands, these islands may be eliminated within a decade. If so, significant natural and cultural resources managed by the NPS, including Fort Massachusetts, will be in peril.

6.4 Barrier Island Restoration Strategy

Given the value of these barrier islands as natural habitat, recreation sites, and possible protection for the mainland to some degree, the following recommendations are designed to address chronic losses in surface area along the islands to restore the natural transport system and island habitat that existed historically. Priority is assigned to East and West Ship Island because these islands have recorded the greatest losses throughout the system and significant cultural resources on both islands are at risk.

6.4.1 Restoration Goals

The overarching goal is to restore the crucial sediment transport system and budget, including littoral zone geologic processes around the Mississippi barrier islands, to a natural state as much as possible given the realities of navigation channel dredging, climate change (sea level rise, increased frequency of storms, etc.) and other anthropogenic activities. Restoring the sediment transport processes of the Mississippi barrier islands to a condition similar to the natural system that functioned before human intervention offers the best opportunity to ensure the long-term viability of these islands.

The preferred restoration approach includes (1) littoral zone deposition of compatible sand, consistent with the quality, especially color, grain size, absence of contaminants, and angularity of sand that would be present in the barrier island system under natural conditions, in appropriate volumes and locations near Petit Bois, Horn and East Ship Islands; (2) up to two small-scale beach nourishment projects on the Mississippi Sound shoreline of West and East Ship Islands to protect historic Fort Massachusetts and the French Warehouse archeological site; and (3) the direct deposition of acceptable beach-quality sand in the area of chronic breaching and inlet formation at Camille Cut to reconstruct the narrow, low sand spit that historically connected East and West Ship Island. The primary objectives of this alternative are to restore the Mississippi barrier island sediment transport system and budget disrupted by anthropogenic activities conducted near these islands, facilitate the restoration of Ship Island to a natural condition, and reduce erosion threats to significant cultural resources.

This preferred restoration strategy would also provide for (1) additional scientific investigations and modeling on which project planning, restoration benchmarks, goals, monitoring protocols and adaptive management prescriptions will be based; and (2) restoration of the regional sediment transport processes, including at a minimum the bypassing of all beach-quality sediment dredged from the navigation channels near the Mississippi barrier islands, and the proper placement of such sediment in the littoral system to replicate natural coastal geologic processes and provide for the protection and preservation of these nationally significant islands.

The sand placement strategy considered for restoration of Ship Island is based on the general geomorphic characteristics of the circa 1916-1917 shoreline and island land mass. The 1916-1917 baseline condition represents the most recent shoreline data available which documents a continuous Ship Island (Rosati et al., 2007; Morton, 2007). Applying data presented in Rosati et al. (2007), this baseline condition also represents a time frame prior to significant increases in maintenance dredging rates and thus volumes of sand removed in the Horn Island Pass Outer Bar Channel which began to occur in 1949. The land mass that connected East and West Ship Islands in 1916-1917 was a narrow, low sand spit measuring approximately 1000-feet wide (north-south width) with a likely elevation of approximately five (5) feet.

The volume of sand necessary to achieve the prescribed “emergency actions” and “advanced engineering and design actions” described below is based on the premise that the 22 million cubic yards of sand removed from the Horn Island Pass Outer Bar Channel during the period of 1909-2005 should be properly placed back into the sediment transport system to restore the barrier islands. In addition, sand removed from the Horn Island Pass Outer Bar Channel during future maintenance dredging operations should be properly placed west of the channel to mimic the natural sediment transport system.

6.4.2 Emergency Actions

Emergency actions would include direct placement of compatible sand on the Sound shoreline of West Ship and East Ship Islands to protect the integrity of historic Fort Massachusetts and the French Warehouse archeological site, direct placement of compatible sand in Camille Cut to suture (fill-in) the existing gap between East and West Ship Islands to a circa 1916-1917 geomorphic condition, and concurrently placing compatible sand in the littoral zone near East Ship Island.

Beach renourishment to protect the integrity of Fort Massachusetts and the French Warehouse archeological sites would include the direct placement of approximately 100,000 cubic yards of beach-quality sand along the Sound shoreline of West Ship Island to protect Fort Massachusetts, and direct placement of about 100,000 cubic yards of beach-quality sand on the Sound shoreline of East Ship Island to protect the French Warehouse archeological site. Sand source locations, compatibility requirements, precise depositional locations, depths of sand deposition, etc., would be

determined by the NPS and USACE. A second round of direct sand placement at the same volumes and locations is contemplated within five years following initial emergency beach renourishment to protect these significant cultural resources until such time as restoration of the barrier island sediment transport system and budget is achieved through additional planned actions described below.

In order to restore the 1916-1917 geomorphic condition of Ship Island, approximately 7 million cubic yards of compatible sand would be directly placed in the Camille Cut breach and inlet area to reconnect East and West Ship Islands (Figure 3). The proposed dimensions of the Ship Island breach restoration project are three (3) miles in length, 1000 feet wide (north-south width), with a proposed sand thickness of approximately six (6) to 14 feet to achieve the desired five (5) feet subaerial elevation across the restored spit reconnecting East and West Ship Islands. However, the anticipated volume of sand required to achieve these restoration dimensions could be slightly modified based upon the results of a planned bathymetric survey of the breach area by the USGS. The sand placement approach would be adaptively managed based on monitoring of project performance measures. The restored sand spit would be planted with native vegetation species (e.g., seaoats, bitter panicum, etc.) to hold the sand in place and to foster future entrapment of wind-blown sand and long-term island stabilization. Native vegetation species would be planted in 60 feet swaths and no closer than approximately 100 feet from both the Gulf and Sound shorelines.

Sand placement in the littoral zone near East Ship Island is essential for continued nourishment to the restored spit at the Camille Cut breach and inlet. Approximately 10 million cubic yards of beach-quality sand would be placed within water depths affected by normal to moderate wave action and no deeper than 15 feet, the USACE definition of maximum littoral zone depth for this area (Hallermeier, 1981 (USACE Coastal Engineering Tech. Aid No. 81-2)) over a large area on the south-southeast side of East Ship Island. This phase of restoration is essential for supplying sand to the beaches west along Ship Island, including those occupying the reconstructed connecting spit. Westward sand transport from the reconstructed spit will also nourish the shoreline near Fort Massachusetts through natural alongshore currents in the Sound. Detailed planning for such deposition in the littoral zone near East Ship Island would be subject to the results of additional research and modeling efforts, including near-shore bathymetry and numerical modeling of waves, currents, and sediment transport.

During and following the placement of sand in all the aforementioned restoration locations, the effectiveness of such placement should be evaluated for success as part of an adaptive management strategy. If metrics indicate successful performance for island restoration and littoral zone placement, projects will continue as planned. Otherwise, at the end of year one, a reassessment and potential change in location for littoral zone placement may be implemented. Successful performance should be based on several factors, including, but not limited to, proper sand placement to nourish the islands and to protect Fort Massachusetts and the French Warehouse archeological site for the next 20 years without a need for annual or repetitive maintenance. Additional sand placement and native vegetation replanting may be required, depending upon success rate, to achieve the desired percent cover.

6.4.3 Advanced Engineering and Design Actions

This restoration strategy will also include the proper placement of approximately 5 million cubic yards of beach-quality sand in the littoral zone updrift of Petit Bois Island in water depths affected by normal to moderate wave action and no deeper than 15 feet. In addition, this strategy proposes to place all sand removed during maintenance dredging operations from the Horn Island Pass Outer Bar Channel to the west of the channel and east of Horn Island so that the dredged sand remains within the littoral zone. The bypassed sand will also be placed in water no deeper than 15 feet. Such

bypassing of sand transported to Horn Island is essential to the long-term health and maintenance of downdrift islands (Horn, East and West Ship Islands). It is estimated that approximately 1 million cubic yards of sand will be bypassed every 2.5 years.

Detailed planning for such deposition in the littoral zone near Petit Bois and Horn Islands would be subject to the results of additional research and modeling efforts, including near-shore bathymetry and numerical modeling of waves, currents, and sediment transport. During and following the placement of sand in the littoral zone near Petit Bois and Horn Islands, the effectiveness of such placement should be evaluated for success as part of an adaptive management strategy. If metrics indicate successful performance for littoral zone placement, projects will continue as planned. Otherwise, at the end of year one, a reassessment and potential change in location for littoral zone placement may be implemented.

6.4.4 Long-term Restoration Actions

Restoring and replicating the sediment transport processes and budget of the Mississippi barrier islands to a condition similar to the natural system that functioned before human intervention offers the best opportunity to ensure the long-term viability of these islands. Therefore, the best long-term restoration solution is to plan for the bypassing of compatible sand routinely dredged from navigation channels in the area that are located east of Petit Bois and Horn Islands. Appropriate volumes of sediment would then be available in the littoral zone transport system to replenish sand lost from all of the Mississippi barrier islands due to natural geologic processes. Any long-term planning to achieve this objective must be based on sound scientific information and understanding of the barrier island sediment budget and transport system, and must be consistent with NPS mandates.

6.4.5 Data Collection, Analysis and Modeling

Prior to implementing the recommended barrier island restoration actions presented above, additional data collection, analysis and numerical modeling must be completed to ensure that project design is based upon the most current scientific information and understanding of the sediment transport system and budget. Recommended data collection and analysis needs include:

- conduct bathymetric survey throughout the island chain and inlets to document water depth in Camille Cut between East and West Ship Islands, identify sand resource targets, and update the existing sediment budget related to island restoration (Figure 6.5-4);
- analyze U.S. Coast Survey topographic maps of Ship Island prepared in 1848, 1853, and 1917 to confirm the subaerial elevation of the narrow sand spit in the central part of the island during that period;
- obtain current orthophotography to document island geomorphology and vegetation characteristics as part of CHARTS data acquisition, and to derive high-water shoreline position for each barrier island;
- acquire seismic and vibracore data at dredged material disposal site locations identified by comparing the modern bathymetric survey to the 1917/18 survey;
- determine sedimentologic characteristics of existing dredged material disposal sites to verify the quantity of sand available for barrier island restoration;
- review past dredged material placement quantities and locations relative to the regional sediment budget; and

- review historical breaching and breach closure data for all islands, and assess available geologic and morphologic data for Ship Island relative to the other barrier islands, to determine why Ship Island has breached several times, whereas Horn Island and Petit Bois Island have not.

To adequately design sand placement throughout the system and to evaluate potential impacts of the no action and preferred alternative scenarios, numerical modeling of waves, currents, and sediment transport should be conducted. Modeling analysis will validate the regional beach response to evaluate dredging and placement alternatives, and restoration of East and West Ship Islands. All historical data since the mid-1800s will be utilized in developing and calibrating the model so that future evolution (decades to a century) can be estimated with and without anthropogenic activities. Recommended modeling tasks include:

- develop input data for the Cascade Model, including shoreline position, topographic cross sections, sediment sources and sinks, vegetation composition and density through time, aerial photographs, storm and typical wave, wind, and water level data, and incorporate spatial data into the existing MsCIP sediment budget GIS;
- calibrate and validate Cascade (including sub-modules: breaching, wind-blown sand and dune building);
- demonstrate application of Cascade for proper dredged material placement, interim beach fills, and large-scale renourishment;
- evaluate placement locations for dredged material disposal at Horn Island Pass and Ship Island Pass for effective bypassing of littoral sand to mimic the barrier island natural sediment transport processes;
- conduct wave climate and surge modeling with and without the Ship Islands to assess potential impact on the mainland; and
- conduct salinity modeling to predict change in the salinity regime under present conditions, without the islands, and with a restored Ship Island (continuous island across the present location of Camille Cut).

6.5 Adaptive Management Strategies for Mississippi Barrier Island Restoration

Adaptive management strategies employed during the restoration project will provide the means to monitor the progress of the project, to assess whether immediate or short-term impacts are those intended or unintended, and a means to halt or modify project activities, or to mitigate the effects of activities, should negative or adverse impacts to natural or cultural resources be noted during monitoring. Monitoring activities should be continued for a specified time period after project activities are completed to measure long-term or cumulative impacts, and whether the goals of the project have been met.

6.5.1 Monitoring Protocols

Monitoring during and following the implementation of the barrier island restoration actions described above is needed to assess the progress of the restoration and short- and long-term impacts to the barrier island system and cultural resources. Monitoring recommendations include:

- obtain orthophotography of each barrier island on an annual basis to determine shoreline position change;

- map bathymetry in the barrier islands area pre- and post-project, 1 year after project completion, 5 yrs after project completion, and immediately following passage of a tropical storm or hurricane to document movement of sand placed in Camille Cut and in the littoral system;
- use topographic, bathymetric and hyperspectral sensors on the Compact Hydrographic Airborne Rapid Total Survey (CHARTS) system to document land elevation and vegetation density change annually, and process and analyze acquired data in an efficient and timely manner to make adjustments in sand placement strategies if desired results are not being achieved; and
- obtain daily real-time water quality data adjacent to all beach renourishment, direct placement and littoral zone placement areas in coordination with EPA Gulf of Mexico, MS Department of Marine Resources and MS Department of Environmental Quality.

During the barrier island restoration process, information obtained through the adaptive management monitoring protocols outlined above will be reviewed by a committee consisting of representatives from NPS, USGS, USACE, NOAA and the State of Mississippi. This committee would determine whether the restoration objectives were being met, and if not, whether sediment placement strategies should be modified or terminated.

6.5.2 Barrier Island Restoration Success Benchmarks

Suggested benchmarks to use to measure the degree of success of the restoration project include:

- 80% vegetation survival in the Camille Cut fill area two (2) years following completion of replanting efforts;
- absent a storm of record, Ship Island should remain continuous for 20 years, and expected minor breaches that occur should heal within 10 years;
- rate of accretion along the western edge of Ship Island should respond as it did in the historical record based upon the best available scientific information; and
- sand placed in the littoral system east of Horn and Petit Bois Islands should result in restoration of the east ends of these islands as measured by an increase in the surface area or a significant decrease in the rate of surface area loss documented during the past two decades.

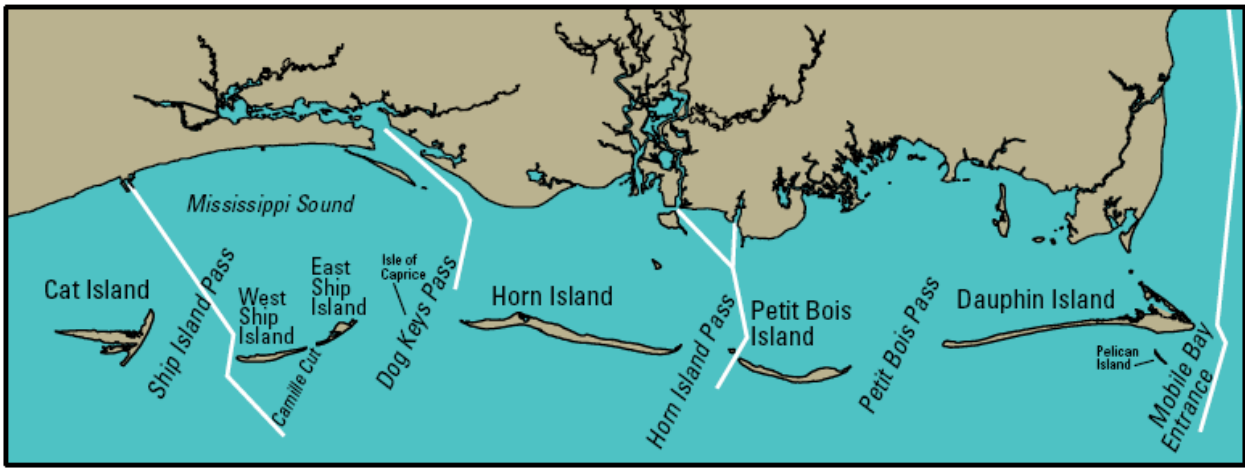

Figure 6.5-1. Locations of the Mississippi-Alabama barrier islands and associated tidal inlets. Deep draft shipping channels maintained by periodic dredging are show as white lines. (from Morton, 2007)

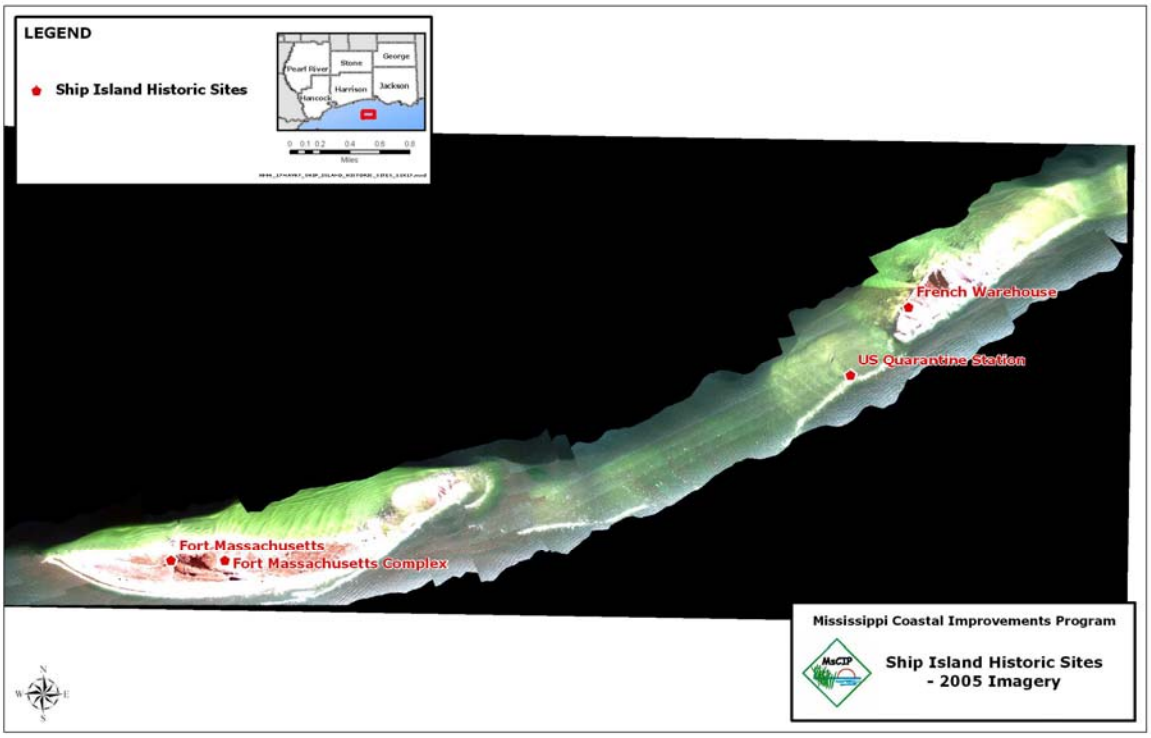

Figure 6.5-2. Aerial photo of West and East Ship Island taken in 2005 after Hurricane Katrina showing the locations of listed cultural resource sites. Note the presence of Camille Cut tidal inlet adjacent to the east end of West Ship Island.

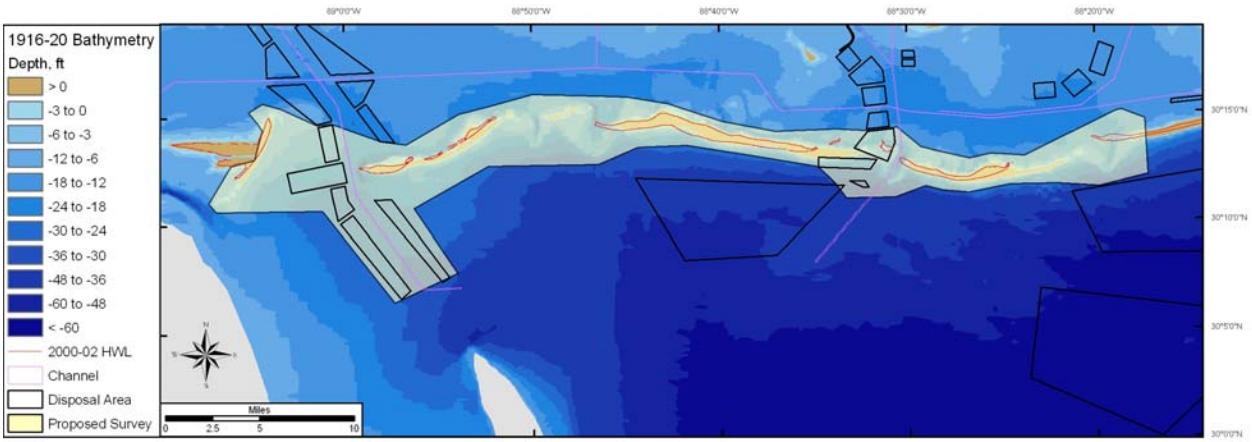

Figure 6.5-4. Proposed location (outlined in the light blue area surrounding the barrier islands) for modern bathymetry survey for identifying potential sand resource targets and updating the existing sediment budget related to island restoration.

CHAPTER 7 THE COMPREHENSIVE BARRIER ISLAND PLAN

7.1 General

The Comprehensive Barrier Island Plan is recommended for construction and will consist of the combination of two engineering options for the barrier islands combined with recommended changes in the local Regional Sediment Management practices. This alternative is recommended to help prevent the accelerated erosion of the barrier islands, especially what is now West and East Ship Island (a single island prior to Hurricane Camille) as well as Petit Bois Island to the east. The National Park Service has endorsed a restoration of islands as described below based on the anthropogenic activities that have compartmentalized the Gulf Islands National Seashore based on national interests including shipping, cultural resources, federally listed species and Essential Fish Habitat components. Stabilizing the outermost barrier islands appears to be the best way to ensure the Mississippi Sound and coastal shoreline ecosystems remain intact. These islands also are the first natural features that protect the coastal counties of the State Mississippi.

To provide needed data on some aspects of completing this plan, additional studies will be conducted during the Engineering and Design (E&D) phase of this project. It is generally understood that the loss of these islands will change the entire ecosystem of the Mississippi Sound as well as having affects on the amount of storm damage incurred along the mainland coast. Since the islands form the Mississippi Sound estuary, continued loss of the islands will allow a different salinity interface as fresh water from the mainland river systems and the salt water from the Gulf of Mexico adjust to new tidal and littoral currents. Under E&D, additional storm surge, wave, water quality,and sediment transport modeling will be conducted to predict the affects of not having West and East Ship Island in place during future hurricanes. Initial modeling indicate that taking Ship Island(s) out of the system will not have a great effect on surge, but will have a major impact on waves that affect the mainland. The additional sediment transport modeling will also be used to optimize the placement of sand in the littoral zone under this plan. Water quality models will also be conducted to predict the changes to salinity levels in the Sound without Ship Island.

Immediately following Hurricane Katrina, the State of Mississippi proposed restoring the barrier islands back to a pre-Hurricane Camille condition with the concept that this would reduce storm surge on the mainland. Analysis of the land loss among the four islands indicated that from 1917 to 2006 (post-Katrina) over 1600 acres of the islands had been lost. To return the islands back to a 1917 footprint (when there was good data available), a supply of beach quality sand would be required that was estimated at 66,000,000 cubic yards. The quality of the sand source would need to be similar in color, grain size, and roundness to the sand that currently comprises the barrier islands. The NPS had concerns over the State's proposal in that it directly contradicted their policy of letting nature take its course unless it was to restore the activities of man or to protect historical sites within Park boundaries. As modeling efforts to evaluate storm surge were being conducted, a sensitivity analysis was performed on different restoration changes to the barrier islands. These results indicated that reductions in surge would not be large, but that the increase in wave heights would be significant if the barrier islands eroded away. Other studies by the USGS and ERDC showed a continuing trend in erosional loss of the islands and that West and East Ship Island would probably be totally lost in the future. Loss of the islands would also be expected to drastically change the ecology of the estuary formed between the islands and the mainland. With all these considerations, the NPS and the Corps formulated a plan (referred to as the NPS Plan) for the barrier islands that would help mitigate some of the loss at the islands and prolong the existence of the islands. This plan includes direct placement of sand to fill a breach in Ship Island, commonly called Camille Cut,

that has existed since Hurricane Camille, add sand to the littoral zone in two areas, and to propose changes in the disposal practices of littoral zone sediment removed from local navigation channels.

7.2 Additional Studies - Littoral Zone Placement and Cat Island Coastal and Ecological Processes and Confirmation of Borrow Areas

Prior to any placement of sand, additional modeling is required to confirm the quantity and quality of sand in borrow areas, better define the optimal locations for the littoral zone placement and obtain additional data needed to understand the ecology and geomorphic fate of Cat Island.

7.2.1 Confirmation of Offshore Sand Borrow Areas

After funding is obtained, an acoustic survey will be conducted in some areas near the barrier islands to identify areas that may contain sufficient sand to use in both direct island and littoral zone placement at Ship Island. These areas will be both disposal areas where disposal from maintenance dredging may have concentrated usable material and sediments that have been pushed out and deposited with the ebb tide currents at the pass west of Ship Island. Any deposits that have useful quantities will be sampled to test for quality requirements. If these surveys fail to located suitable material, the program will then concentrate on the submerged islands that make up St. Bernard Shoals that lie south on the barrier islands. To verify the quantity of sand available for borrow at St. Bernard Shoals and to obtain physical samples for quality characteristics, a geophysical survey and sampling program will be conducted.

7.2.2 Optimal Littoral Zone Placement

The model that was completed and described in Section 3.0 will be used as a basis to further study the optimal locations to place both littoral zone additions of sand and the locations for disposal of material from future maintenance dredging.

7.2.3 Cat Island Coastal and Ecological Processes

Cat Island has a different coastal process that has been identified, but not thoroughly investigated. The littoral zone currents that help replenish the other Mississippi barrier islands does not cross the pass between West Ship Island and Cat Island to the west. The formation of the Mississippi River delta cut off the path of the historic littoral current and had left Cat Island without the natural nourishment of sand. Little information is available on Cat Island, but the additional study will include not only coastal processes, but also ecological processes that will provide valuable information on the little known habitat on Cat Island.

7.3 Camille Cut and Barrier Island Restoration

West Ship has migrated westward along the littoral drift zone with the western end of the island now terminating against the deep-water, Gulfport navigation channel that prevents further drift. Studies (Rosati, 2007) have confirmed that West Ship Island is the last active island system in the littoral zone that originates in northwest Florida. The same type of land loss exists for Petit Bois Island where the east end is migrating westward and the western end is now terminated against the Pascagoula navigation channel. Records indicate that over 22 million cubic yards of sediment have been removed for maintenance from the Pascagoula Channel since it was created. This quantity of sand was used as the basis of adding sand back into the littoral system since, theoretically, this sand

would have continued its transport along the littoral system. Three measures were adopted to return this sand into the system. The first would be to fill the three mile breach in Ship Island, Camille Cut, to a 1000-foot width and a height that would require approximately 13-million cubic yards of sand including loss during placement and the re-nourishment of some erosion along the northern shore. The other two measures would be to add sand into the littoral system with about 5-million cubic yards going into the area east of East Ship Island and the rest (4-million cubic yards) going to the area east of Petit Bois Island. Placing more sand at Ship Island is assumed because of the accelerated erosion that has taken place there. The quantities of material assumed for the littoral placements would be subject to change after additional sediment transport modeling if this modeling indicates this adjustment.

Loss of these islands from the barrier islands chain will have severe impacts to both cultural and ecological resources in Mississippi. The islands play a major role in maintaining the ecosystem of the Mississippi Sound. The various types of vegetation found on the islands provide habitat to many species including endangered birds such as Least Tern and Piping Plovers. Oysters, shrimp and many species of fish depend on the role the islands play in maintaining lower salinity levels found within the Sound and the presence of these species are tremendously important to the local economy and provide a way of life for the thousands of local residents employed by the seafood industry. The many miles of beaches associated with the islands also provide recreation for tens of thousands of visitors annually.

The pre-Camille footprint of Ship Island was obtained from historical records and this data showed that the island was breached during Hurricane Camille in 1969 forming two separate islands as mentioned above. This breach had been partially filled with a sand spit extending westward from East Ship Island when Hurricane Katrina again opened the breach in 2005. As happened during Hurricane Camille, the new breach was formed leaving two islands with approximately three miles of open water between the remaining portions. West Ship Island has been experiencing severe erosion in some areas because of the loss of sand in the system from the ebb tidal flows through the breach. East Ship Island is also losing land mass as the sand in its system migrates into the breach area. Currents studies (USGS, 2007 and Rosati, 2007) indicate that West and East Ship will probably not recover from their current severely eroded state.

West and East Ship Island also have two major historic sites that are in danger from the continuing erosion of the barrier islands. The presence of these historic sites led to the inclusion of the barrier islands off the coast of Mississippi as a National Seashore. Current studies by the Corps indicate that restoring the two islands to a single island, pre-Camille condition may prevent the rapid erosion of the beaches that is now occurring at these sites and aid in the reduction of erosion that is endangering Historic Fort Massachusetts on West Ship Island.

The addition of sand into the littoral system on the eastern ends of East Ship and Petit Bois Islands will provide a sediment source for the islands and help mitigate any affects from the maintenance of the navigation channels. The additional sediment transport modeling will include modeling to predict the optimal location for the placement of sand into the littoral zone near the islands to provide a source of sand for the natural healing on the breach.

The quantity of sand required for these options are considerably less than the total restoration of the islands, but still substantial. To fill the breach, the sand would have strict requirements on color, grain size, and roundness. In discussions with the USGS, a potential source of sand was identified at St. Bernard Shoals which is a submerged chain of barrier islands approximately 45 miles south of the Mississippi barrier islands. Both quality and quantity are assumed to be available, but further investigations are required to verify the source. Activity from oil and gas production in the local area must also be considered. As described above approximately 13,000,000 cubic yards of the high quality sand are needed to fill the breach. An additional 5,000,000 cubic yards of sand is being

proposed for placement into the littoral zone east of East Ship Island. This sand would still have physical compatibility characteristics to the sand in the littoral system that must be considered. The last measure of the plan would be to add approximately 4,000,000 cubic yards of compatible sand into the littoral zone east of Petit Bois Island. The source of this sand is proposed to be from the inland river system that flows into Mobile Bay if additional quality testing demonstrates it's compatibility with sand within the littoral system. While maintaining channel depths, sand is dredged from these rivers and placed in numerous upland disposal areas along the river. The lower Tombigbee River has several million cubic yards of sand stored along its banks that may be useful for the littoral zone placement. Due to the location of the disposal areas, this sand is being considered for use for the Petit Bois Island littoral zone placement. This source will provide the beneficial use of sand and at the same time provide additional dredged material storage capacity along the river system. The sand in the disposal areas has a tan color as opposed to the whiter sand on the barrier islands, but this is believed to be a iron staining that will obtain a good color match after placement in the littoral zone and being transported (and abraded) by the transport process. The quantity of sand required for littoral zone east of Petit Bois is available along the lower Tombigbee River and can easily be transported down the river and over to the island. It was assumed that 20% of this sand would be lost in handing. If this sand source proved not to be compatable, the sand would be obtained from sources used for Ship Island.

Also during the E&D phase, another potential source of sand would be investigated that would be much closer to the project site and would also allow the beneficial reuse of dredged material. This further study would look at historical disposal areas for the Gulfport navigation channel that crosses through the littoral zone. The sediments that are removed from the channel during routine maintenance dredging have been placed in approved disposal areas that have been used for an extended period of time. While the material placed in these areas was not segregated by grain size, there may be substantial quantities of beach quality material that has potential use at Ship Island, either for filling Camille Cut, adding to the littoral zone, or both. Reuse of the sediments from the disposal areas would follow Regional Sediment Management practices that promote keeping sediments in the littoral system and/or beneficial use of material that is removed during both new and maintenance dredging.

In this same local area, recent sediment transport studies have shown that westward sediment migration has been affected by the southward extension of the Mississippi River delta. This extension has cut off the littoral current and terminated the westward migration of sediments in the pass in the vicinity between Cat and West Ship Island. The fate of these sediments has not been determined, but there may be a large deposit of sand that could be used at Camille Cut or replaced in the littoral system.

The placement of sand to fill Camille Cut and the two large littoral zone placements are planned as one-time events to restore some of the islands land surface that may have been lost to erosion from mans past activities or from mass erosion during storm events. This decision was based on an agreement with the NPS that allows them to mitigate ay damage from mans activities or to perform necessary means to preserve historic sites. This agreement has a positive aspect to MsCIP with the replacement of sand that has been lost from the littoral system. This sand addition will extend the life of the islands and the closure of Camille Cut will help maintain the boundaries of the estuary. It is understandably difficult to quantify either of these sand loss causes because the barrier islands themselves are dynamic systems that are undergoing constant change

7.4 Regional Sediment Management Issues

The presence of two deepwater navigation channels that pass through the littoral zone have created artificial boundaries to the westward migration of the islands. The continued maintenance of these

channels will require that sand and other sediments be removed, but under the guidelines of the Regional Sediment Management Practices, the sand removed from the channels will be returned to the littoral system. The placement of this sand in the future will be supported and guided by the results of additional focused sediment transport modeling that will be conducted prior to any placement.

This continuing study would evaluate future placement of maintenance material dredged from the Pascagoula Harbor Navigation Channel. It has been recommended that sand from the channel be placed down-drift in a newly designated disposal area located in the littoral zone near Sand Island. Much of the sand dredged in the past was placed down-drift, but was formed into a small island commonly called Sand Island. Sand Island has become a prime environmental resource vegetated with dune grasses that provide habitat to many types of shore birds. With no further sand additions, the sand within this islands will probably return to the littoral system as wind and currents erode the land mass.

Material removed from the Gulfport Channel has historically been placed in disposal areas south of the littoral zone. In keeping with the guidelines of the Regional Sediment Management Practices, revised recommendations will be made to more properly dispose of the material removed from the littoral zone segment of the channel so it will have improved beneficial use. The existing channel alignment is at the western tip of West Ship Island and is a trap for the migrating sand. It has been recommended to study and model placement zones that will maximize the benefits of deposing of this sand. This practice will allow the sand to continue to nourish the barrier islands and slow the erosional processes of the land masses. How to best achieve this will be considered in the continuing study of the islands. Initial ideas include immediate reuse by littoral zone placement or stockpiling high quality sand in selected disposal areas so the material would be readily available in the future for relocating the sand into the littoral zone as needed. The disposal areas that are currently designated may be used or additional areas could be defined.

7.5 Long Term Monitoring Program

Monitoring during and following the implementation of the barrier island restoration actions described in this plan is needed to assess the progress of the restoration and short- and long-term impacts to the barrier island system and cultural resources. Monitoring recommendations include:

- Task 1 - Obtain orthophotography of each barrier island on an annual basis to determine shoreline position change annually for five (5) years and for an additional three (3) events every two (2) years;
- Task 2 - Map bathymetry in the barrier islands area pre- and post-project, 1 year after project completion, 5 yrs after project completion, and immediately following passage of a tropical storm or hurricane to document movement of sand placed in Camille Cut and in the littoral system;
- Task 3 - Use topographic, bathymetric and hyperspectral sensors on the Compact Hydrographic Airborne Rapid Total Survey (CHARTS) system to document land elevation and vegetation density change annually, and process and analyze acquired data in an efficient and timely manner to make adjustments in sand placement strategies if desired results are not being achieved; and
- Task 4 - Obtain daily real-time water quality data adjacent to all beach renourishment, direct placement and littoral zone placement areas in coordination with EPA Gulf of Mexico, MS Department of Marine Resources and MS Department of Environmental Quality.

7.6 Emergency Sand Placement for Fort Massachusetts and French Warehouse

An emergency project to place sand in two areas is being included in the Comprehensive Barrier Island Restoration Plan. This sand placements is to protect Fort Massachusetts on West Ship Island and the French Warehouse site on East Ship Island from damage or destruction from erosion of the northern beaches at their respective locations. This project has been requested by the National Park Service to mitigate the recent storm damage to these two historic sites. This project was included in the Main Report Section 5.3.14 - Public Input and Review of Planning Options, Round One, but was not selected in the initial group of Interim Projects because of extensive coordination that was required by multiple agencies. This effort made it impossible to meet the short time frames required for the Interim Projects.

CHAPTER 8 COST ESTIMATES

8.1 General

The Comprehensive Barrier Island Restoration Plan has many study components will be included within the "Engineering and Design" cost based on the estimated contract cost. These studies were requested as part of the overall plan, but will be covered under the required studies for design. They include the Optimal Littoral Zone Placement and Cat Island Coastal and Ecological Processes. Studies that will have an additional cost are associated with a recommended monitoring plan to document from the pre-construction conditions at the barrier islands, then for about ten years post-construction. The summary costs for the Comprehensive Barrier Island Restoration Plan is shown in Table 8-1. The local Regional Sediment Management Practice team has been heavily involved in the Mississippi barrier island study and will make revisions to their operating practices at the Mississippi Barrier Islands. These changes will not have a direct cost to the Comprehensive Barrier Island Restoration Plan.

Table 8-1.
Summary of Costs for the Comprehensive Barrier Island Restoration Plan

Project Sub-item	Costs
Sand Placement, Ship Island Breach and Littoral Zones	$516,000,000
Long Term Monitoring	$4,950,000
Cat Island Cat Coastal and Ecological Processes and Optimal Littoral Zone Placement	$0 (see note)
Regional Sediment Management Practice Revision	$0 (see note)
Emergency Sand Placement, Fort Mass and French Warehouse	$3,000,000

Note: As described in Section 8.1, these cost are incorporated into the Engineering and Design costs for the "Sand Placement, Ship Island Breach and Littoral Zones"

8.2 Construction (Sand Placement) Costs

The Total Project Costs for the construction associated with the barrier island restoration will include all costs that were described in Options C1, C2 and G under the LOD-1 estimates in the Cost Appendix. These detailed costs were combined into a single estimate and is included in Table 8-2.

8.3 Monitoring Program

The total costs for the long term monitoring program (over a period of 11 years) as described in Section 7.5 are included in Table 8-3. The tasks are fully described in Section 7.5.

8.4 Emergency Sand Placement, Fort Massachusetts and French Warehouse

An emergency project to protect Fort Massachusetts on West Ship Island and the French Warehouse on East Ship Island has been requested by the National Park Service to mitigate storm damage to these two historic sites. This project was included in the Main Report Section 5.3.14 - Public Input and Review of Planning Options, Round One, but was not selected in the initial group of Interim Projects because of extensive coordination that was required by multiple agencies. This effort made it impossible to meet the short time frames required for the Interim Projects. The cost for this project is included in Table 8-4.

Plan Formulation Appendix

FOREWARD

This document is one of a number of technical appendices to the *Mississippi Coastal Improvements Program (MsCIP) Comprehensive Plan and Integrated Feasibility Report and Environmental Impact Statement*.

The *Mississippi Coastal Improvements Program (MsCIP) Comprehensive Plan Integrated Feasibility Report and Environmental Impact Statement* provides systems-based solutions and recommendations that address: hurricane and storm damage reduction, ecosystem restoration and fish and wildlife preservation, reduction of damaging saltwater intrusion, and reduction of coastal erosion. The recommendations contained in the Main Report/EIS also provide measures that aid in: greater coastal environmental and societal resiliency, regional economic re-development, and measures to reduce long-term risk to the public and property, as a consequence of hurricanes and coastal storms. The recommendations cover a comprehensive package of projects and activities, that treat the environment, wildlife, and people, as an integrated system that requires a multi-tiered and phased approach to recovery and risk reduction, irrespective of implementation authority or agency.

The MsCIP Study Area

The purpose of the Comprehensive Plan Report is to present, to the Congress of the United States, the second of two packages of recommendations (i.e., the first being the "interim" recommendations funded in May 2007, and this "final" response, as directed by the Congress), directed at recovery of vital water and related land resources damaged by the hurricanes of 2005, and development of recommendations for long-term risk reduction and community and environmental resiliency, within

the three-county, approximately 70 mile-long coastal zone, including Mississippi Sound and its barrier islands, of the State of Mississippi.

The USACE has taken a system wide approach in formulating the Mississippi Coastal Improvements Program (MsCIP) Comprehensive Plan to ensure that both the MsCIP and the Louisiana Coastal Protection and Restoration (LaCPR) efforts are fully coordinated and develop complementary plans for the restoration of the U.S. Gulf coastal region as an integrated system.

In addition, the planning effort has taken a "top down" comprehensive planning approach, beginning with development of a Comprehensive Plan to address the overall water resources problems and opportunities of the region. Building off of the comprehensive identification of problems and opportunities, the planning effort then proceeded to develop site specific problems, opportunities and solutions that contribute to accomplishing the Comprehensive Vision for the restoration and protection of the Mississippi Gulf Coast. The results of this effort are a comprehensive regional plan that addresses hurricane and storm damage reduction and environmental restoration needs, as well as recommending a variety of site specific projects for either immediate implementation or for further investigation and subsequent implementation.

The analyses presented in this Plan Formulation Appendix support recommendations for approval of the Comprehensive Plan and for immediate implementation for a variety of water resource development projects that were developed through the comprehensive planning process. The Plan Formulation Appendix also supports recommendations for additional study for those components of the Comprehensive Plan which require additional investigations prior to identifying a specific recommendation for construction.

This appendix, the Main Report/EIS, and all other appendices and supporting documentation, were subject to Independent Technical Review (ITR) and will be presented for an External Peer Review (EPR). Both review processes will have been conducted in accordance with the Corps "Peer Review of Decision Documents" process, has been reviewed by Corps staff outside the originating office, conducted by a Regional and national team of experts in the field, and coordinated by the National Center of Expertise in Hurricane and Storm Damage Protection, North Atlantic Division, U.S. Army Corps of Engineers.

This Plan Formulation Appendix presents problem areas identified by stakeholders and residents of the study area, a summary of the approach used in analyzing problems and developing recommendations directed at assisting the people of the State of Mississippi in recovery, recommended actions and projects that would assist in the recovery of the physical and human environments, and identification of further studies and immediate actions most needed in a comprehensive plan of improvements for developing a truly resilient future for coastal Mississippi.

The MsCIP also developed and employed risk-based concepts which engaged stakeholders and allowed for informed decision making. The MsCIP planning process made extensive use of public and agency involvement, which introduced ideas, provided feedback, and gave first-hand accounts of the damages suffered as a result of the disaster. In an effort to demonstrate reliable public service professionalism, the public, state and local government input received at public workshops was also used to identify the degree of importance placed on environmental issues and to give indication of the likely Locally-Preferred Plans, should those be pursued as options to more cost-effective recommendations, consistent with Federal guidelines.

The results of the planning process (as expressed in the Systems of Accounts tables):

- identify cost-effective solutions,

- provide the best choices based on an extensive set of criteria, and
- identify the trade-offs made during the evaluation of alternatives.

The System of Accounts tables present the culmination of technical analyses, public input, and systematic evaluation. The selected alternatives stand out in their ability to fulfill the Congressional authorization and the needs of the nation.

This appendix contains detailed technical information used in the analysis of existing and future without-project conditions, in the development of problem-solving measures, and in the analysis, evaluation, comparison, screening, and selection of alternative plans. Each appendix functions as a complete technical document, but is meant to support one particular aspect of the feasibility study process. However, because of the complexity of the plan formulation process used in this planning study, the information contained herein should not be used without parallel consideration and integration of all other appendices, and the Main Report/EIS that summarizes all findings and recommendations.

1 THE MSCIP PLANNING PROCESS – REACHING BEYOND THE TRADITIONAL PROCESS

The process of developing technically sound, environmentally sensible, cost-effective, publicly acceptable, and comprehensive solutions to the problems caused by the hurricanes of 2005, and with the potential to be caused by future events, required a thorough, and highly iterative process. This process had to incorporate both traditional planning requirements (which have served the nation well), as well as a more direct process of identifying and fully discussing potential risks and consequences of any given action, in a way that all might participate in, and understand the full meaning of.

This Appendix follows the plan formulation process in its applied sequence, and each step of this process must be fully laid out, to understand how the study team formulated plans, screened measures and alternatives, and arrived at a cost-effective, environmentally beneficial, and technically sound package of recommendations.

Plan formulation for the Comprehensive Plan utilized the highly-successful process discussed in Corps of Engineers' Engineering Regulation 1105-2-100 (also known as the "Planning Guidance Notebook"), with the addition of a number of new tools required in this specific study effort, including an extensive set of tools and evaluative and screening processes involving the potential risks and consequences of any action.

The directive language for the Mississippi Coastal Improvements Program included the requirement to address not only hurricane and flood (storm) damage, but also coastal erosion, fish and wildlife preservation and recovery, and salt water intrusion. Additionally, the study language also specified a different approach toward identification of a plan, in that it specifically directed that the report "shall recommend a cost-effective project", and furthermore, that the report "shall not perform an incremental benefit-cost analysis...and shall not make project recommendations based on maximizing net national economic development [NED] benefits..". This guidance demanded that the study team both develop an approach that met those mandates, while not deviating significantly from the traditional Federal planning process.

The MsCIP planning process uses the familiar Corps and NEPA study processes, which compare and contrast measures and alternatives for a full range of anticipated impacts and effects, with the former also requiring a "System of Accounts" analysis. Because the study area is so large and diverse, however, the mandates so broad, and the consequences of exceedance or failure so potentially catastrophic, the study effort also required that the Plan Formulation process be more iterative and risk-aware than is usually the case. The process had to be capable of re-visiting each and every assumption and piece of data, and modifying the measures developed as solutions, so as to create the most cost-effective package of potential options for review by decision-makers. This is also reflected in the study recommendations. Cost-effectiveness was determined by comparison of implementation costs to that of the damage reduction benefits each measure would provide.

The MsCIP study utilized an additional evaluative tool to address risks and consequences of potential alternatives, by use of a Risk-Informed Decision Framework (RIDF), to allow comparison of highly disparate factors affected by plan implementation, particularly those factors that were not dealt with well under the traditional Corps planning process. A key component of this process was the "weighing-in" of the public and other decision-makers, which reflect the factors most important to them, in deciding what might be done to address identified problems. Most notable among these factors were the potential risks (including residual risks), to population, environmental recovery and preservation, cultural, aesthetic and historic resources, and other factors that remain very difficult to

compare and contrast. The Risk-Informed Decision Framework process is discussed in great detail in the RIDF Appendix.

The MsCIP process integrated a highly inclusive public and agency involvement process. This process was critical in the conduct of plan formulation activities, in that it introduced ideas, provided feedback, and gave first-hand accounts of the damages suffered as a result of the disaster. Public input (which included local and State governmental input) received at these public workshops was also used to define the "weight" of factors discussed above (such as the degree of importance they placed on environmental issues) examined in the Risk and Consequences analysis of potential plans, and to give indication of the likely direction of Locally-Preferred Plans, should those be pursued as options to more cost-effective recommendations.

Finally, the tentative recommendations derived by this process and presented in the Comprehensive Plan may be used as guidelines concerning the most cost-effective solutions, the best choices for a given set of criteria, and the trade-offs required. These are the tools required by local government and residents in the selection of plans that best meet their needs, and the needs of the nation.

1.1 The Traditional Federal Planning Process

The traditional Federal planning process has served this nation well. It has allowed the development of thousands of water resource projects that have prevented billions of dollars in damages, and saved countless lives. Unfortunately, it has also not always addressed the difficult-to-evaluate elements of risk and consequences, both of failure, and also of residual risk not addressed by projects, in situations both where the design event is exceeded, and also where different choices are made that may affect future conditions. It has also not necessarily accommodated the values of residents and decision makers in the analysis and selection process, in particular in weighting factors, which are of particular importance to concerned interests other than economic factors.

Recent guidance has reinforced the need to utilize methods capable of evaluating factors that resist quantification by traditional means, as part of the plan formulation and selection process. This includes means by which a study team might evaluate the trade-offs inherent in any design, those of residual risks inherent in each design, and also those of factors that are difficult to evaluate and prioritize under the traditional process.

The six traditional Planning Steps include:

1) Identifying Problems and Opportunities
2) Inventorying and Forecasting Resources
3) Formulating Alternative Plans
4) Evaluating Effects of Plans
5) Comparing Alternatives
6) Selecting the Recommended Plan

1.1.1 The MsCIP Comprehensive Plan – The Planning Process

The planning process utilized in the MsCIP study was a highly iterative process, which actually went beyond that done in the traditional six-step Corps feasibility study planning process. This was required, due to the fact that new problems or data were constantly being identified, but also because analysis of comprehensive plans, such as a "Lines of Defense" (LOD), constantly brought new problems and opportunities to light, requiring modification of, or development of, new measures; and the analysis, evaluation, and comparison that this requires.

A key element of the modified planning process utilized for the MsCIP study also included an additional sub-step of forecasting and analyzing not only one future "without-project" scenario, but a

series of potential future scenarios, including highly speculative future re-development, and relative sea level rise scenarios.

In addition, and as discussed above, the addition of a RIDF, which evaluates the risks and consequences of a certain action, required additional sub-steps to be inserted in this process.

The sequence of steps developed for the MsCIP effort (*with additional sub-steps or iterative steps italicized*) can be shown in figure 1 and included:

1) Identifying Problems and Opportunities (*or Further Refined)*
1a) Constraints Identified (*or Further Refined)*
2) Inventory and Forecast Resources *(and Define Multiple Future Without-Project Scenarios)*
3) Preliminary Measures Developed for Each Problem Area (*followed in later iterations by formulation of true alternative plans*)
4) Evaluation of Effects of Measures (*followed later by Alternative Plans*)
5) Comparing Measures (*followed in later iterations by comparison of Alternatives*)
5a) Measure Screening by Traditional Initial Screening Criteria - Technical, Environmental and Economic Feasibility (*followed in successive iterations by screening by progressively more rigorous criteria)*
5b) Refinement of Measures - Development of Data at Higher Level of Detail, on Remaining Plans, in concert with development of data on other impact areas such as cultural, environmental, etc. effects.
5c) Development of metrics, units of measure, etc., for Risk Evaluation
5d) "Weighting" of Risk metrics by residents of coastal Mississippi
5e) Risk-Informed Decision-Making with Refined Data.
5f) Final presentation of measure and/or alternative outcomes , including benefits, costs, risks, and consequences, to decision-making population
6) Selection and Presentation of Recommendations.

It must be pointed out that addition of these sub-steps, additional iterations, and inclusion of risk-based analysis is not an exclusive process, but a complementary process, that ensures a more rigorous identification of risks and consequences, and also greater inclusion of the public in a decision-making process.

The plan formulation process actually began during the Interim Phase of study, with development of a comprehensive list of problem areas, consisting of single or multiple problems associated with a given site or resource, and identified as having been caused or exacerbated by the hurricane events of 2005. Each of the problems identified were related to one of the four key areas of: a) hurricane storm damage, b) coastal zone erosion, c) damage to fish and wildlife resources, and d) saltwater intrusion.

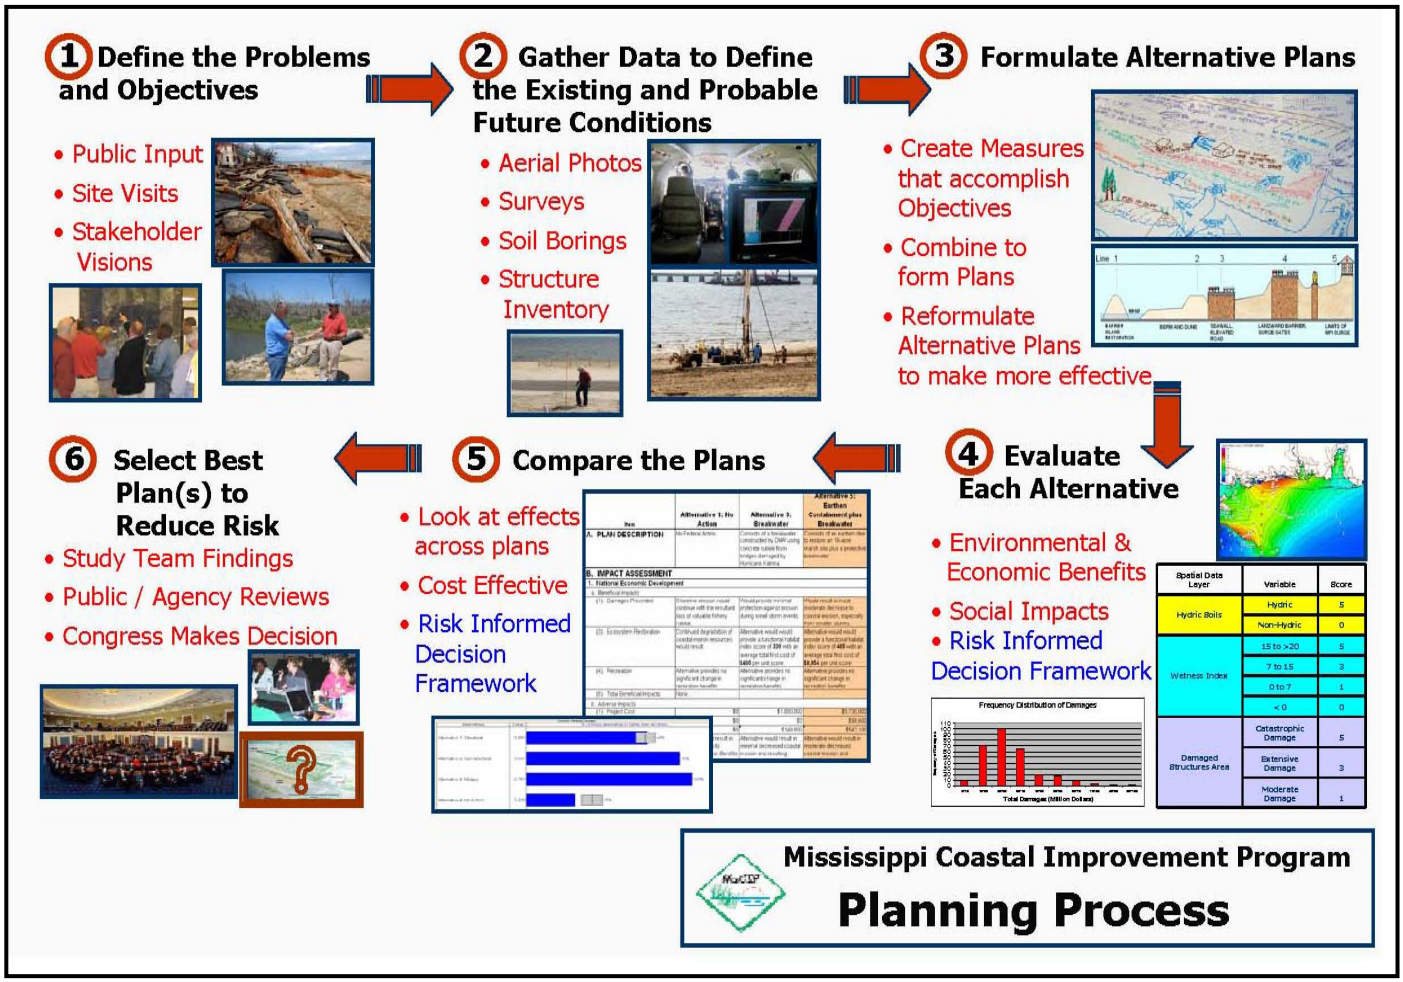

Figure 1 The MsCIP Planning Process

1.1.2 Internal Technical Review and External Peer Review

Internal Technical Review (ITR) was lead and coordinated by the Corps' National Center of Coastal Storm Damage Reduction Expertise, at the North Atlantic Division. ITR involved the use of experts in many fields, from multiple disciplines, and located in numerous parts of the country. ITR was conducted as a completely separate enterprise from internal technical review quality control, and quality assurance. No member of the ITR team was involved in any aspect of the study effort but that of independent technical review of products.

ITR consisted of multiple levels of review, at several points in the process. Details on the timing, sequencing, and disciplines engaged, are contained in the ITR / External Peer Review (EPR) Appendix.

The EPR was coordinated by the Corps' Baltimore District. No member of the District was involved in this wholly-external review process. The EPR process was lead by the Batelle Corporation, a private company with expertise in this particular requirement. Batelle staff chose the members of the EPR team from the ranks of academia, private concerns, and other sources of particular expertise. At no time were the names of credentials of any member of the EPR team shared with any member of the study team, but all EPR team members represent highly qualified individuals in those specific

fields of endeavor. EPR was also conducted as a completely separate enterprise from internal technical review quality control, quality assurance, or independent technical review. No member of the EPR team was involved in any aspect of the study effort but that of external peer review of products.

EPR consisted of a single level of review. Details on the timing, sequencing, and disciplines engaged, can be found in ITR / EPR Appendix.

1.1.3 Introduction to Addressing Risks and Consequences

The approach chosen by the study team on the MsCIP Comprehensive Plan effort was a multi-layered assessment, evaluation, and presentation of risk, uncertainties, and consequences.

Risks and uncertainties were evaluated and incorporated into numerous technical analyses, such as the degree of uncertainty the coastal engineer felt about wave heights, surge heights, or storm behavior. Risks and uncertainties were also accounted for in the technical analysis of ecosystem functions values, and long-term project performance. Risks and uncertainties were also evaluated for a variety of economic indicators, and for multiple future without-project scenarios, including those of relative sea level rise, and of multiple future re-development scenarios.

The MsCIP Comprehensive Plan phase of study utilized an additional evaluative tool to address risks and consequences of potential alternatives, by use of a “RIDF”, which allowed comparison of highly disparate factors affected by plan implementation, particularly those factors that were not dealt with well under the traditional Corps planning process. A key component of the RIDF process was the “weighing-in” of the public and other decision-makers, which reflected the factors most important to them, in deciding what might be done to address identified problems. Most notable among these factors were the potential risks (including residual risks), to population, environmental recovery and preservation, cultural, aesthetic and historic resources, and other factors that remain very difficult to compare and contrast. The Risk-Informed Decision Framework process is discussed in great detail in the RIDF Appendix.

In addition, the team also spent a great deal of effort evaluating the risks, uncertainties, and consequences of any given action, outside that framework, so that complete and unbiased information on those factors could be presented and evaluated, by the broadest possible group. Information on risks, uncertainties, and consequences (including that of residual risk), is presented in both the table of factors used in the RIDF process, but also as a separate System of Accounts category, for full disclosure in that process, also. Key in this recognition of risks, uncertainties, and consequences, was also the recognition of multiple future without-project scenarios, most importantly those addressing uncertainties in the behavior of human beings and political realities within the study area, and those of uncertainties regarding sea level changes and subsidence.

1.1.3.1 Accommodating Uncertainty in Future Re-Development Through Scenario Testing

Field surveys were conducted to observe structure and content characteristics, where damages occurred, and the magnitude of damages incurred by Hurricane Katrina. The magnitude of structures that sustained significant damage, 50% or more structural damage and would have to completely rebuilt, was significant. It was estimated from the field surveying of structures that 32,446 structures within the study area sustained this level of damage; 9,555 in Hancock County, 16,528 in Harrison County, and 6,363 in Jackson County.

Given the magnitude of the long-term rebuilding effort, two re-development scenarios were identified. The first scenario is the full redevelopment of structures as existed pre-Hurricane Katrina

to exactly what they were before the storm (i.e. if a structure was a residence before it will rebuild as a residence, a condominium will rebuild as a condominium, etc.). The second scenario includes the full re-development of the study area to its pre-Katrina levels but differs slightly from the first re-development scenario with respect to the coast line, which would see commercial re-develop. This scenario is based on observations of re-building efforts in other counties and states along the Gulf Coast and Florida Panhandle following Hurricane Ivan in 2004. Those re-development efforts suggest that a large portion of the beach front and back bay areas may re-develop to condominium structures. In addition to condominiums, current Mississippi law allows casinos to be built in these counties on land within 100-feet of the Mississippi Sound.

These re-development scenarios are intended to determine the level of risk of future surge events depending on the types of development that might be seen in the future. They were coupled with various levels of relative sea level rise and evaluated to determine the extent of plan performance, expected annual damages, and residual damages of flood damage reduction measures using the Hydrologic Engineering Center - Flood Damage Analysis (HEC-FDA) Monte Carlo Simulation program. More detail on these scenarios can be found in the Economic Appendix to this report.

1.1.3.2 Accommodating Uncertainty in Future Sea Level Rise Through Scenario Testing

Systematic long-term tide elevation observations suggest that the elevation of oceanic water bodies is gradually rising and this phenomenon is termed 'sea level rise.' The rate of rise is neither constant with time nor uniform over the globe. Present estimates of recent (over about the last 100 years) global average, or eustatic, sea level rise are varied but the average value is about 2 millimeters per year. Sea level is rising due to global warming, and there is uncertainty as to the future rate of sea level rise, how much sea level will rise at any particular location, what the primary drivers of global warming really are, and whether the rate of rise will be relatively constant or accelerate. Regardless of these uncertainties, more than half of the world's population lives near the sea, and sea level rise is a phenomenon which requires society's sustained attention and requires planning with consideration to the needs and protection of future generations.

Preliminary analysis of available data suggests a 20th century relative sea level rise of nine inches along the Mississippi coast. Relative sea level rise is what an observer standing on the shoreline over a long period would observe and includes the combined effects of land subsidence (or uplift) and the rise of sea level in and of itself. For the last twenty five years, the climate change community has also been arguing that sea level rise will accelerate in the 21st century, though to date, there is no clear confirmation that an acceleration is actually taking place, and the rates at which sea level rise is predicted to accelerate have been somewhat inconsistent. There is therefore some uncertainty as to the future prevailing natural environment which a proposed project must function within. Society relies on project performance. Therefore, it is important to recognize that sea level has been rising, and it's prudent (and required by USACE regulations) to recognize inherent uncertainties by exploring the ramifications of varying levels of possible relative sea level rise scenarios on project performance. This present study employs sensitivity analysis to do so. Sensitivity analysis is nothing more than an exercise where one changes an assumption and examines how outputs change accordingly. There are two primary assumptions that are modified in this program. The first is the magnitude of the relative sea level rise over the evaluation period. This program examines the implications to project performance for existing sea level; expected (i.e. moderate, or 'central value') relative sea level rise of about 2 feet; and high relative sea level rise of about 3.4 feet. Changes to these inputs provide a sense of project robustness (i.e. how well does the project perform over a range of uncertain futures?) and vulnerability (i.e. if a future materializes whereby the project would fail, how bad would the failure be?). Additionally, project performance is evaluated at a lifetime of 50 years; changes to the project lifetime provides insight as to the value over time of the initial investment, and whether an investment might be better delayed into the future,

or whether more significant investments might be required in the future than might be expected, amongst other considerations. Numerous outputs are examined according to these alternative scenarios, including expected annual damages, damages reduced, and the annual probability of a surge level being exceeded.

2 IDENTIFYING PROBLEMS AND OPPORTUNITIES

Problem areas and sites, and opportunities associated with those sites, were solicited from, and then discussed, with members of the public, state, local, and other Federal agencies, representatives of industry and commerce, and resource agencies concerned with study area resources, at the series of open meetings, at individual meetings, and through other open forums. The meetings also included web-casts intended on reaching those that could not physically attend one of the in-field meetings.

2.1 Problems

Hurricane-caused problems were also investigated in a series of on-going site investigations conducted in partnership with local representatives, to ensure a complete grasp on the nature of all identified problems, and to ensure development of a full range of suitable measures and plans to deal with the identified problems. The general nature of ***problems*** identified by the study team, State, County, and City officials, residents, and agency staff, included:

- Hurricane-induced storm surge and wave damage to structures and infrastructure within a specific site/problem area;
- Hurricane-induced storm surge and wave damage to structures and infrastructure within the entire three-county study area (analyzed as both specific areas, depending on the siting of the measure, but also as an entirety as a specific problem area);
- Hurricane-induced storm surge and wave damage to specific ecosystems/sites/problem areas within the identified three-county area;
- Hurricane-induced storm surge and wave damage to the entirety of all ecosystems within the entire three-county study area (analyzed as both specific areas, depending on the siting of the measure, but also as an entirety as a specific problem area);
- Hurricane-induced saltwater intrusion within the Mississippi Sound ecosystem and associated coastal environments;
- Hurricane-induced erosion of specific coastal wetlands and coastal infrastructure.

To facilitate the gathering of information, several workshops and public meetings were held in each county. Lists of the identified problems from each meeting are provided in Tables 1 through 15.

Table 1.

Coastal-wide Stakeholder Input: Coordination with Local Communities

Item#	Name
1	Coastal Mississippi Hurricane Evacuation Plan
2	Coastal Mississippi Artificial Reef Project for Remediation of 2005 Hurricane Damage

Table 2.

Coastal-wide Stakeholder Input: Regional Coordination Workshops

Item#	Name
3	Wetland area buy-outs
4	Barrier Islands - Restoration
5	USE selected levels of rip-rap instead of bulkheads for erosion control
6	Replace structures with marshes.
7	Provide 100 acres of oyster reef restoration
8	Work with State to authorize transfer of development rights in state statute
9	Include repair standards in building codes
10	Dredge access channels to existing public marine industry and recreation
11	Review main drainage systems to determine where improvements are most necessary and will decrease future erosion and/or failure issues
12	Improve comprehensive retention/detention systems in each entity to reduce rainfall-related flooding.
13	Form a monitroing network network that will survive and function throughout a major storm to provide data that is critical to emergency managers
14	Provide an incentive for replacing failing septic systems in rural areas to improve water quality along bayous and bays.
15	Implement a barrier or check valve system to isolate freshwater detention from saltwater inundation during surge events.
16	Add wetlands along main drainage systems in each location to increase capacity of the systems during rainfall and surge flooding events.
17	Complete snagging/clearing, etc. to restore the capacity of existing drainage.
18	Repair existing bulkheads or other structural drainage components that were damaged during the storm to reduce future failures during similar events.
19	Maximize Beneficial Use of Dredge Materials
20	Consider brown water system to minimize demand on ground and surface waters and limit saltwater intrusion.
21	Re-establish Benchmark Information Coastal-wide
22	Relocate wastewater treatment facilities out of the surge-prone areas
23	Inspect and Rehabilitate Wastewater and Piping Systems
24	Develop additional Offshore Breakwaters or Sand Dunes where determined most Beneficial through Modeling
25	Barrier Islands - Combat invasive species
26	Consider all archaeological sites in planning process Many significant coastal sites are eroding and need to be preserved.
27	Barrier Islands - Sensitivity towards barrier islands
28	Barrier Isalands - Remove hazardous materials
29	Barrier Islands - Develop Baseline Flora-Fauna Studies
30	Barrier Islands - Protect From Spills
31	Barrier Islands - Evaluate Sediment Transport - Ensure sand minimg does not Impact Islands
32	Barrier Island - Indicate NPS boundaries on project maps
33	Marsh Restoration where Feasible This can be done in conjunction with private and government dredging projects
34	Partnership Efforts with Louisiana to Marsh Island Areas

Table 3.

Coastal-wide Stakeholder Input: Public Workshops

Item#	Name
35	Barrier Islands - Restoration (to a natural setting)
36	Allow nature to dictate wetlands vs. beach to a greater degree.
37	Provide protection for public facility (i.e., WW treatment plants).

Table 4.

Hancock County Stakeholder Input: Study Team Coordination

38	Bay St. Louis Downtown HSDR
39	Cowand Point Seawall Erosion Control
40	Hancock County Beach Ecosystem Restoration and HSDR
41	Clermont Harbor Seawall HSDR and Erosion Control
42	Hancock County Comprehensive HSD - Ecosystem Restoration
43	Jackson Wetland Restoration
44	Bayou Caddy Shore Protection and Ecosystem Restoration
45	St. Louis Bay Comprehensive Ecosystem Restoration
46	Lakeshore Beach Ecosystem Restoration
47	Clermont Lake Ecosystem Restoration
48	Hancock County Communities Flood Damage Reduction
49	WhiteÆs Road Evacuation Route Protection

Hancock County Stakeholder Input: Regional Coordination Workshops

50	Biloxi Marshes Comprehensive Ecosystem Restoration
51	Magnolia Branch Ecosystem Restoration
52	Jordan River Shores Ecosystem Restoration. . Buy out landowners, return hydrology, begin mitigation, prohibit new/more development
53	Pearlington Ecoystem Restoration - Buy-out homeowners and return hydrology
54	Shoreline Park buyout

Table 6.

Hancock County Stakeholder Input: Public Workshops

55	Restore more natural freshwater flows by closing the MRGO
56	Remove storm debris (i.e., demolition debris carried in by surge retreat) from aquatic environments. Restore traditional shrimping and fishing areas rendered un-trawlable by storm debris.
57	Ferries to Temporarily Replace Bridges.
58	Restore all Hancock (all cosatal MS) marshes damaged by storm
59	Restore Hancock County Beaches to Pre-Katrina conditions
60	Widen Hancock County Beaches, jump-start dunes
61	Preserve Bayou Caddy Area
62	Protect Hancock County wetlands from filling for development
63	Construct a N/S rail link connecting Port Beinville Industrial Park to the Norfolk and Southern Railroad through Stennis Buffer. Hurricanes cause CSXT rail outages which cost > $20,000/day

Table 7.

Hancock County Stakeholder Input – Additional Input from Regional Coordination Workshops

Item#	**Name**
64	Open the east Pearl River channel so it can be used by commercial marine traffic from Port Bienville
65	Pursue the development of additional breakwater structures in low-use areas.

80	Turkey Creek Flood Damage Reduction
81	North Gulfport Interior Drainage
82	Long Beach Interior Drainage HSDR (includes Canals 2 - 3)
83	Harrison County Industrial Seaway Harbor of Refuge
84	Tchoutacabuffa River Flood Damage and Watershed Improvement
85	Courthouse Road Wetlands Ecosystem Restoration and Preservation
86	Deer Island Ecosystem Restoration
87	DÆIberville Wetlands Ecosystem Restoration
88	Biloxi Back Bay Watershed Management and Ecosystem Restoration

Table 9.

Harrison County Stakeholder Input: Regional Coordination Workshops

Item#	**Name**
89	West Ship Island. Continue to re-nourish the north shore of the island east and in front of Fort Massachusetts, a national historic site.
90	Evaluate Dredging and Channelization when preparing flood controls from rain events to consider impact for storm surge in costal zone.
91	Extend South Side of Deer Island. Extend 200 yards to repair breach in island and restore original footprint of island.
92	Deer Island enhancements. Cap shell middens on western side of the island and restore top soil in maritime live oak forest
93	New Sewage Treatment Plant in Woolmarket Lagoon Area - Move the Woolmarket Lagoon to north of I10 north of the area. would protect the citizens by moving the sewage from the flood prone areas:
94	Flood-Proof Existing Infrastructure
95	Enhance Lee and Bayview Docks for commercial shrimpers.
96	Enhance Maine Street Docks for commercial shrimpers.
97	Acquire wildlife corridors in lands that repeatedly flood
98	Develop Concrete Staging Center in Industrial Canal. Develop Harrison county industrial canal artificial reef staging area to stockpile concrete debris for oyster reef and other useful projects.
99	Restore or enhance Mississippi oyster reefs.
100	Open hw 90 Bridges quickly
101	Utilize HW 90 bridge as artificial reef material
102	Provide Compensation for Persons in Flood-prone Areas to Relocate. Areas prone to flooding, such as Eagle Point, should be offered buy-outs.
103	Economic Development of Downtowns. Orderly expansion of municipal harbors along with revitalization of downtowns would provide green space; non-water dependent retail, and a manageable beach blvd. (NOT HW 90).
104	Turkey Creek: Mt. Pleasant UME Audubon site 41, Tidal Creek restoration of flood plain.
105	Complete the purchase of “optional” Cat Island for inclusion into Gulf Islands Nationals Seashore
106	Rebuild the Harrison County boardwalk with concrete to accommodate pedestrians, BICYCLES, and possibly street vendors.
107	Provide inland marine vessel storm shelter location with adequate moorings.

Table 10.

Harrison County Stakeholder Input: Public Workshops

108	Restore grassbeds in MS Sound
109	Retention/Detention basin to hold runoff while waiting for surge to go down from Brickyard Bayou.
110	Surge gates along Biloxi Bay to help ease drainage areas during storm events
111	Wiers (low level dams) within estuaries to control water flow
112	Purchase riparian buffers, wetland areas.
113	Reconsider dioxin cleanup on navy base post Katrina.
114	Long Beach Interior Drainage HSDR (includes ôCanals 2 - 3)
115	Reduce toxic exposure which exacerbates storm damage – Dioxin, Creosote, Titanium Dioxide, Gypsum.
116	Turkey Creek watershed Greenway
117	Forrest Height Levee :- Restore; Vegetate with native species; Footbridges; Nature trail atop
118	Dredge shoaled channels hinfering storm evacuation
119	Dredge shoaled marinas

Table 11.

Harrison County Stakeholder Input: Additional Input from Regional Workshops

Item#	**Name**
120	Deer Island re-nourishment of south side.
121	Provide protection of public infrastructure from flooding, surges and sedimentation.
122	Possibly add height to the existing beach elevation and redevelop lost dune vegetation.
123	Flood-proof low-lying sewer treatment plants. Lift stations and wells and their electrical and electronic controls.
124	Construct reservoir or detention system to provide storage for rain events to reduce or prevent flooding along coastal rivers.

Table 15.

Jackson County Stakeholder Input: Additional Input from Regional Workshops

188	Improve the Jackson-county seawall. Provide additional county-wide seawall construction, boardwalks, beach construction, marsh construction, or a combination of these elements
189	Gautier improvements to drainage. Same as B.
190	Gautier, drainage improvements. Same as C
191	Bayou Outlets on the Mississippi Sound that require actions to remove deposited siltation
192	Gautier improvements to drainage. Same as D.
193	Dredge Davis & Simmons Bayous to include all connecting bayous to help prevent flooding.
194	Rebuild and enlarge Marsh Island
195	Divert water from Escatawpa River into Bayou Cumbest to restore freshwater flow to the bayou and improve water quality.

Table 3-1 presents a synopsis of system-wide and county problems and related needs identified by stakeholders during the workshops and public meetings. These problems and related needs are the basis for the plan formulation process.

Table 16
Examples of Stakeholder Input: Coordination with Local Communities

Stakeholder Identified Problems	Stakeholder Identified Needs
• Loss of life and human injury due to ineffective communication • Insufficient capacity at storm shelters	• Coastal Mississippi Hurricane Evacuation Plan
• Storm surge damages and environmental degradation due to development in low lying areas	• Wetland Area Buyouts
• Erosion and intrusion of salt water	• Barrier Island Restoration • Restore or enhance Mississippi Oyster Reefs • Freshwater Diversion
• Erosion and storm damage	• Widen beaches, jump start dunes (Hancock, Harrison, and Jackson Counties)
• Storm surge flooding caused damage to structures and infrastructure	• Provide protection for public facilities • Surge gates along Biloxi and St Louis Bays • Seawalls, levees and ring levees (Forrest Heights Levee, etc.) • Hurricane and Storm Damage Reduction at population centers (Gautier, Ocean Springs, etc.) • Floodproof Existing Infrastructure
• Storm surge caused sedimentation in wetland areas	• Restore wetland functions (Grand Bay Swamp, Hancock County Marsh, etc.) • Restoration of Pine Savannah • Complete snagging and clearing to increase flood water conveyance

Additional details on specific problems are provided within the appropriate appendices. For storm damage reduction and erosion control formulation and screening processes, these discussions are contained in the Engineering Appendix. For ecosystem restoration and saltwater intrusion reduction formulation and screening processes, these discussions are contained in the Environmental Appendix. The results of each evaluation and screening process are summarized in the following chapters, and are presented as a Comprehensive Plan of "tentative recommendations" in the Main Report.

2.2 Opportunities

Comprehensive, ***system-wide opportunities*** were identified during the MsCIP planning process to guide the development and evaluation of solutions to the region's water resource problems. An overall theme of Comprehensive Plan opportunities is not merely to reverse the harm done by the hurricanes of 2005, but as importantly to promote the long-term future sustainability of physical,

human, and environmental resources within the study area. Comprehensive, system-wide opportunities include:

- Assist in sustainable redevelopment of hurricane damaged physical, environmental, and human resources within the MsCIP study area;
- Reduce the susceptibility of residential, commercial, and public structures and infrastructure to hurricane induced storm damages within the three-county (Hancock, Harrison, and Jackson) MsCIP study area;
- Assist in the recovery and long-term sustainability of coastal wetlands that support important fish and wildlife resources within the study area;
- Accelerate the recovery and assist in the long-term sustainability of maritime forest environments that suffered hurricane induced damages;
- Restore barrier island environments that suffered hurricane induced storm damages in a manner that promotes long-term sustainability of their fish and wildlife resources;
- Reduce saltwater intrusion within the Mississippi Sound coastal environment;
- Assist in the recovery of coastal ecosystems and infrastructure damaged by erosion during the hurricane events of 2005 and support programs that promote long-term erosion reduction and limit erosion potential during future hurricane events.

2.3 Planning Goals and Objectives

In response to the Federal Goal, as established by Congress, the following goals were established for the MsCIP by the Corps of Engineers Project Development Team (PDT), cooperating agencies and affected public. The system-wide goals established for this study were developed in clear recognition of the linkages between structural and nonstructural storm damage reduction and ecosystem restoration opportunities. System-wide goals are intended to address the coastal landscape of the entire Gulf Region, including the area specifically evaluated in the LaCPR program. MsCIP system-wide goals identified in the Comprehensive Plan effort include the following:

- Identify measures to minimize risk to loss of life and safety caused by hurricane and storm surge;
- Recommend cost-effective measures for restoration of nationally and regionally significant environmental resources within a context of long-term sustainability;
- Recommend cost-effective measures to reduce damages from hurricanes and storms without encouraging re-development in high-risk areas;
- Recommend cost-effective measures to mitigate damages caused by saltwater intrusion into nationally significant ecosystems;
- Recommend cost-effective measures to restore eroded coastal resources as part of a system-wide approach to develop a resilient coastline;
- Identify other water resource related programs and activities integral to the development of a comprehensive system-wide plan.

The system-wide objectives established for this study provide specific targets to measure progress towards achieving the comprehensive goals outlined above. Projects formulated as part of the Comprehensive Plan were evaluated based on their ability to contribute to achieving the targets established in these objectives. System-wide objectives include the following:

- Reduce loss of life caused by hurricane and storm surge by 100%;
- Reduce damages caused by hurricane and storm surge by $150M-$200M annually;
- Restore 10,000 acres of fish and wildlife habitat including coastal forests, coastal wetlands, wet pine savannah, submerged aquatic sea grasses, oyster reefs, and beaches and dunes by the year 2040;
- Manage seasonal salinities within the western Mississippi Sound such that optimal conditions for oyster growth (surrogate for other aquatic resources, 15 ppt during summer months) are achieved on an annual basis by 2015;
- Reduce erosion to barrier islands, mainland, and interior bay shorelines by 50%;
- Create opportunities for collaboration with local, state, and Federal agencies to facilitate implementation of programs and activities that maximize the use of resources in achieving the comprehensive goal.

2.3.1 Planning Considerations: Environmental Justice

On February 11, 1994, President Clinton issued EO 12898, *Federal Actions to Address Environmental Justice in Minority and Low-Income Populations*. The EO is designed to focus attention of Federal agencies on the human health and environmental conditions in minority communities and low-income communities. Environmental Justice analyses are performed to identify potential disproportionately high and adverse impacts from proposed actions and to identify alternatives that might mitigate these impacts.

2.3.1.1 Historic and Existing Conditions

Data from the U.S Department of Commerce, Census of Population and Housing were used for this Environmental Justice analysis. The population in 1990 for Mississippi was 2,573,216. Minority populations included in the census are identified as Black or African American, American Indian and Alaska Native, Asian, Native Hawaiian and other Pacific Islander, Hispanic, of two or more races, and other. Mississippi is only second to the District of Columbia as having the largest Black or African American population. Poverty status, used in this coastal Mississippi report to define low-income status, is reported as the number of persons with income below poverty level. The 2005 Census defines the poverty level as $9,973 of annual income, or less, for an individual, and $19,971 of annual income, or less, for a family of four. In 2005, Mississippi ranked number one out of the 50 states for individuals living below the poverty level in the past 12 months. Unfortunately, Mississippi had 21.3% of its population living in poverty in 2005.

Coastal Mississippi has a lower percentage of minority residents than the State of Mississippi and the U.S. In 2000 (the most up-to-date data available), 79.6 percent of the population was white and 16.3 percent was black. All other racial groups combined totaled approximately 4.1 percent of the population, while 2.2 percent were of Hispanic origin. In Mississippi, 61.4 percent of the population was white, 36.3 percent was black, 2.3 percent was of another minority racial group, and 1.4 percent was of Hispanic origin. For the U.S., 75.1 percent of the population was white, 12.3 percent was black, and 12.6 percent was of other minority racial groups. Approximately 12.5 percent of the U.S. population was Hispanic.

The Census Bureau bases the poverty status of families and individuals on 48 threshold variables, including income, family size, number of family members under the age of 18 and over the age of 65, and amount spent on food. In 1997, approximately 14.6 percent of the residents were classified as living in poverty, lower than the State of Mississippi but slightly higher than the poverty rate for the U.S. as a whole.

2.3.1.2 Post-Hurricane Conditions

As of 2006, the population in Mississippi was 2,910,540 – of this 135,940 individuals live in Jackson County, 193,810 live in Harrison County, and at this time a population count for Hancock County was not available. Hurricane Katrina drew focus on the number of residents unable to flee the Gulf coast due to lack of funds. There is a longstanding legacy of unfair and disproportionate harmful exposures to low income, predominantly African American communities in much of Mississippi. Predominantly in the Biloxi area but also in other coastal Mississippi communities, there was a large population of Asian Americans that depended upon fishing for their livelihood. Adverse impacts from Hurricane Katrina have resulted in a large number of these individuals leaving the area.

Environmental Justices have resulted from years of industrial activity and waste disposal practices that hit these communities harder than higher income, predominantly white communities. Impacted areas, such as superfund facilities, are located more often in low-income areas and therefore are at greater risk to post-Katrina exposure. As clean-up proceeds and rebuilding begins, every effort must be made to remedy these environmental injustices through full clean-up, fair rebuilding practices, and full partnership with affected communities. Over 30,000 families are being helped through Administration on Children and Families Temporary Assistance for Needy Families (TANF) program by the provision of short-term, non-recurrent cash benefits to families who traveled to another State from the disaster designated States. The hurricane-damaged States of Mississippi, Louisiana, and Alabama also received additional funding for the TANF program to provide assistance and work opportunities to needy families ($69 million for loan forgiveness and $25 million in contingency funds for State Welfare Programs.)

Counties along the Mississippi Gulf coast lost a sizeable share of their white residents and homeowners immediately following Hurricane Katrina, while other Gulf Coast metropolitan areas, especially those that gained residents, experienced little overall shifts in their demographic profiles. Coastal counties of Mississippi, which include Gulfport-Biloxi and Pascagoula metropolitan areas, in contrast to New Orleans, were left with a population that had a larger share of minority residents, a lower level of homeownership, and no significant decline in poverty. In essence, while the poor and less well-off residents of New Orleans bore the greatest brunt of Katrina, the storm had a more egalitarian effect on the population of coastal Mississippi. Our examination of the data for other hurricane impacted areas in the Gulf Coast region reveals that while a great deal of population shifting had occurred, only minor changes have taken place in the race and ethnic, economic and socio-demographic profiles for most of these areas.

Each and every measure or alternative examined in the MsCIP study was evaluated for its potential for adverse impacts to minority and/or low-income populations, in adherence with EO 12898. In no case was there any identified negative impact to any of these communities in regards to human health and environmental conditions, from any proposed actions or projects.

Because no plans for structural or non-structural protection of residences or businesses, either in-place or as acquisition and relocation have been vetted by community leaders or the public at more than a concept level, it is impossible to say whether or not any of these measures, as ultimately acted on over the long-term, would genuinely have a significant effect, either positive or negative, on low-income or minority populations.

In fact, the realities of living in a high hazard area, which grows more hazardous as one approaches the shoreline, will supersede the effect of any plans or projects pursued under any outside authority. The reality is that most low-income populations, some of whom are also minorities, will have a hard time rebuilding in high hazard areas simply due to the cost of homeowners or business insurance, which will be a requirement of the vast majority of lending institutions. In the more than two years since the hurricanes of 2005, the majority of rebuilding has been undertaken by those that can self-

insure their homes or businesses, and also afford to rebuild with their own resources, something the vast majority of low income families cannot do. Therefore, the economic nature of communities along the coast of Mississippi is being changed largely by the economics of those that can afford to rebuild and insure their properties, versus those that cannot.

And, while some structural measures might protect areas in which low-income residents might rebuild, those measures would only provide damage reduction for surge events, and not wind. The cost of insurance against wind damage, which would continue to be a requirement of lending institutions, may continue to drive the economics of whether one can or cannot afford to rebuild traditional residences or businesses, within the highest hazard zones.

Non-structural measures intended for acquisition and removal of the most risky structures would tend to affect all residents or businesses located in those zones, low-income and high-income alike. However, well-armored structures, such as high-rise concrete complexes, would advisedly be the most survivable of those that might exist in the most high hazard zones. But, the choice of income level of those that would be able to afford to live in those complexes, will also likely be driven by the economics of those that can or cannot afford to do so. Whether or not some of those complexes can afford to contain apartments that have low rental rates, will be a choice of local government, which controls zoning ordnances and land-use and development decisions. Ultimately, the plan adopted for the Mississippi coast will not be a plan forced on them by the Corps or other Federal agencies, but a plan coordinated, discussed, and finally adopted by the numerous entities and individuals that will live with that plan, the residents and local government of coastal Mississippi.

3 DISCUSSION ON TECHNICAL ANALYSES: PLANNING AND ENGINEERING METHODOLOGIES AND APPROACHES

The technical analyses undertaken by the MsCIP study team involved the development of methodologies and application of models, over a broad spectrum of disciplines. These include economics, environmental resources, plan risk evaluation and decision-making, coastal engineering, design and cost estimating, real estate, geotechnical investigations, Geographic Information Systems (GIS) application, saltwater/freshwater interface and saltwater intrusion remediation analysis, erosion and sediment transport analysis, sediment source analysis, hydrology and hydraulics, public involvement, and plan formulation.

Details on each of these technical functions and evaluative efforts are given in each of their respective appendices; however, a general discussion of the process each engaged in, in the development of measures and alternatives, is provided in following sections of this report.

3.1 Planning Models

Planning models used in the development, evaluation, and screening of measures, are provided in Table 17, below. A more complete discussion on all the models used throughout this study, as well as quality control and quality assurance procedures can be found in the Modeling Appendix.

Table 17.

MsCIP Planning Models

Model	Description/Purpose	Use in MsCIP
Spatial Decision Support System (SDSS)	GIS based decision system to identify & evaluate potential sites	Selection of potential Wetland restoration sites
AL/MS Gulf Coast Tidal Fringe Hydrogeomorphic Model (HGM)	Perform functional assessment of tidal fringe wetlands	Evaluate positive/negative impacts to tidal fringe wetlands
MS Wet Pine Savannah HGM Model	Perform functional assessment of wet pine savannah habitats	Evaluate positive/negative impacts to wet pine savannah habitats
Functional Habitat Unit (FHI) Spreadsheet	Assess the environmental Values of beach and dune habitat	Evaluate positive/negative impacts to beach and dune habitats

3.2 Environmental Resources Analysis and Evaluation

The analysis of existing and future "without-project" resources, and the development, evaluation, and screening of measures and alternatives dealing with ecosystem degradation and restoration, are discussed in general terms below, and in more detail in the Environmental Appendix.

The environmental team initially defined the overall comprehensive natural system and its condition after the hurricane season of 2005. This detailed discussion is found in Chapter 1 of the Environmental Appendix. A comprehensive list of ecosystem-related problem areas consisting of single or multiple problems associated within a given site was compiled with assistance from members of the public, state, local, and other Federal agencies, representatives of industry and commerce, and resource agencies concerned with study area resources, at a series of open meetings and on-site meetings. These areas were first identified as having been caused or exacerbated by the 2005 hurricane events identified with: a) coastal erosion; b) damage to fish and wildlife resources; and c) saltwater intrusion. The vast areas initially identified for study of ecosystem damage are shown in Figures 2 - 4. The areas are color designated based on their ability to be restorable. The red designation shows areas that are highly likely to be able to be restored to their historical habitats and in contrast the blue designation shows areas that are possible but very difficult to be able to be restored.

After an initial screening of problem areas to determine their link to the hurricanes of 2005, a list of potential problem-solving measures was developed for each problem area. This list of problem areas and sites damaged by the hurricanes of 2005 was then screened based on the input of the inter-disciplinary study team's understanding of each site's ability to either heal on its own, unaided by human intervention, or:

- by its national and/or regional significance in regards to the type of ecosystem it represents;
- the need for assistance to restore vital hydrologic links;
- the need to manually remove blockages created by hurricane-deposited debris that was impacting function;
- the need to remove excess sediment deposited by the hurricanes that had changed the nature of the land's surface and resulted in degraded function and value;
- the need to remove invasive species that had entered the area since the hurricanes and caused displacement of native plant species (and potentially wildlife depending on native species), degrading function of the ecosystem; or

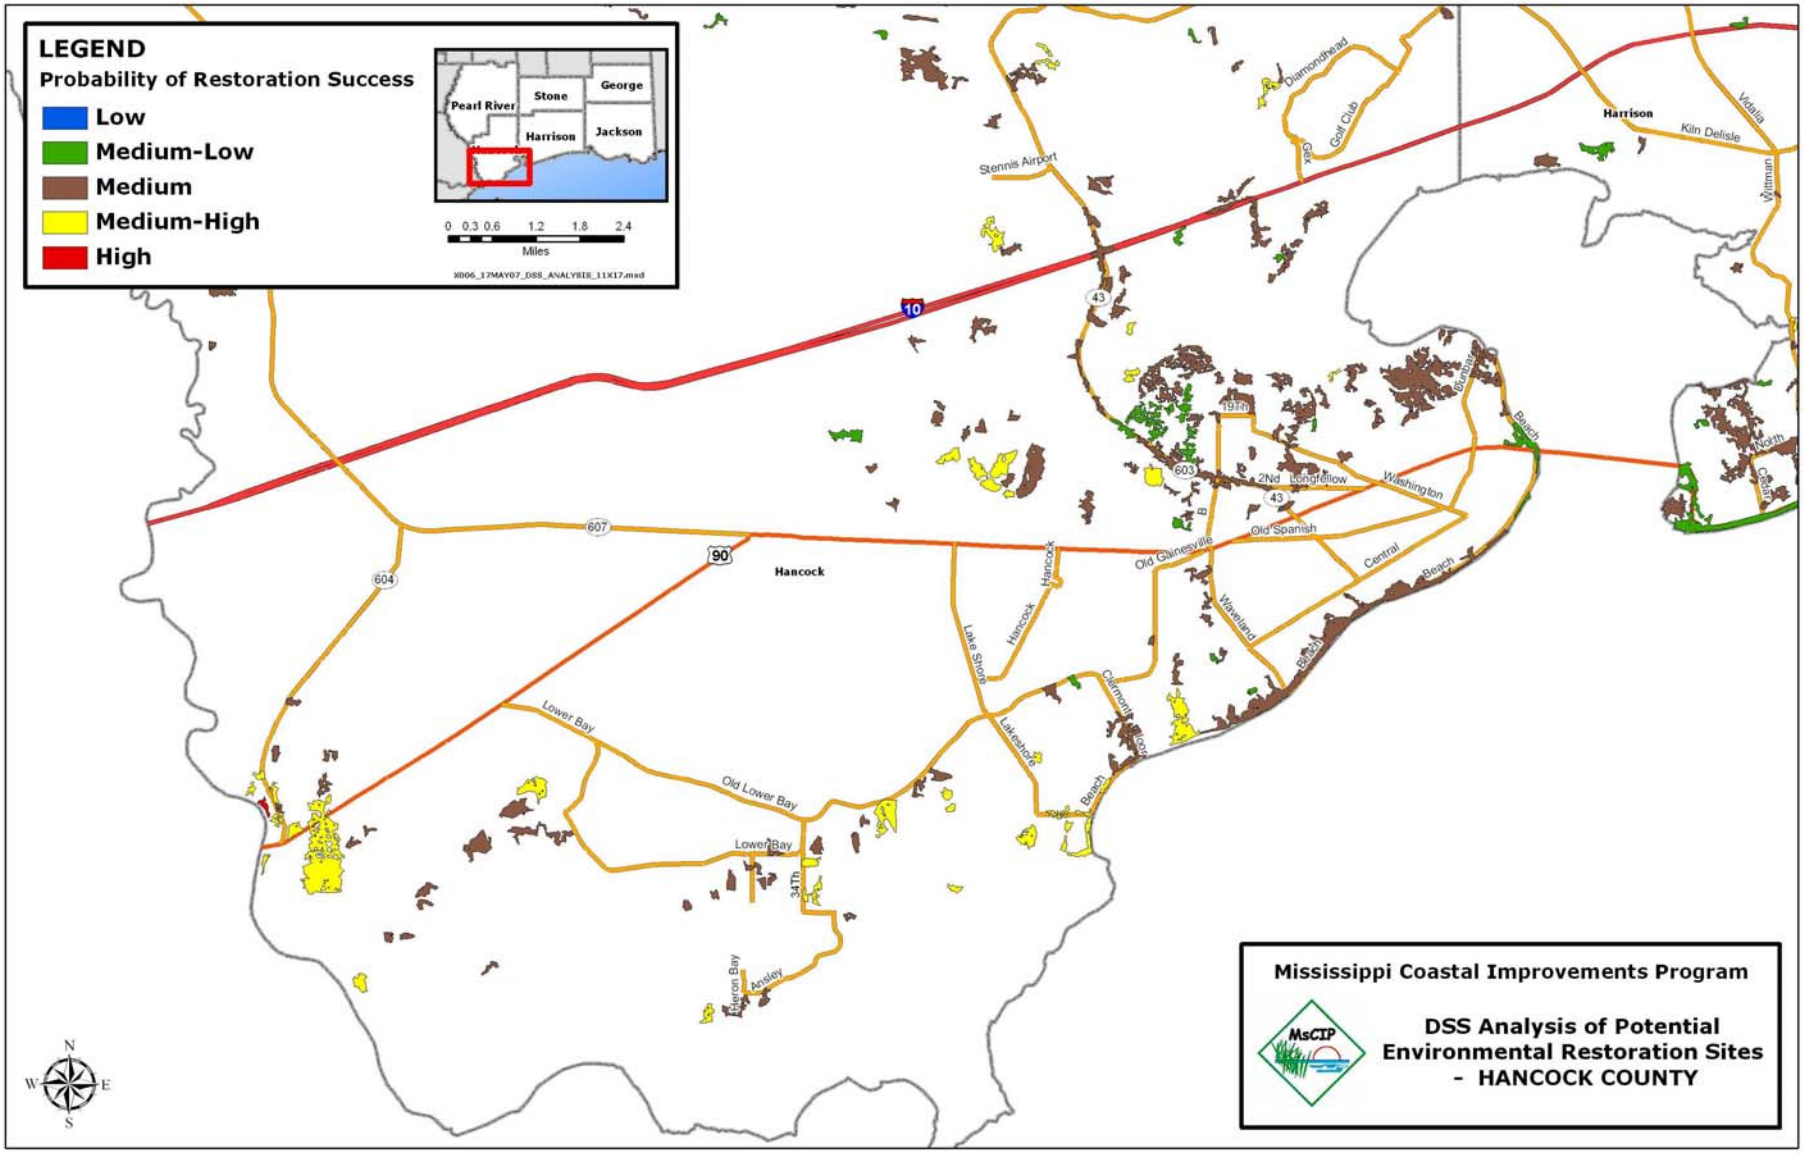
- the need to plant native species vital to restoration of a significant ecosystem and restoration of its functions and values.

The following four models were utilized by the MsCIP environmental PDT to evaluate existing and future without-project conditions within the three-county study area:

- Mississippi and Alabama Gulf Coast Tidal Fringe Hydrogeomorphic (HGM) model;
- Wet Pine Savannah HGM model,
- SDSS; and
- Functional Habitat Index (FHI) Model.

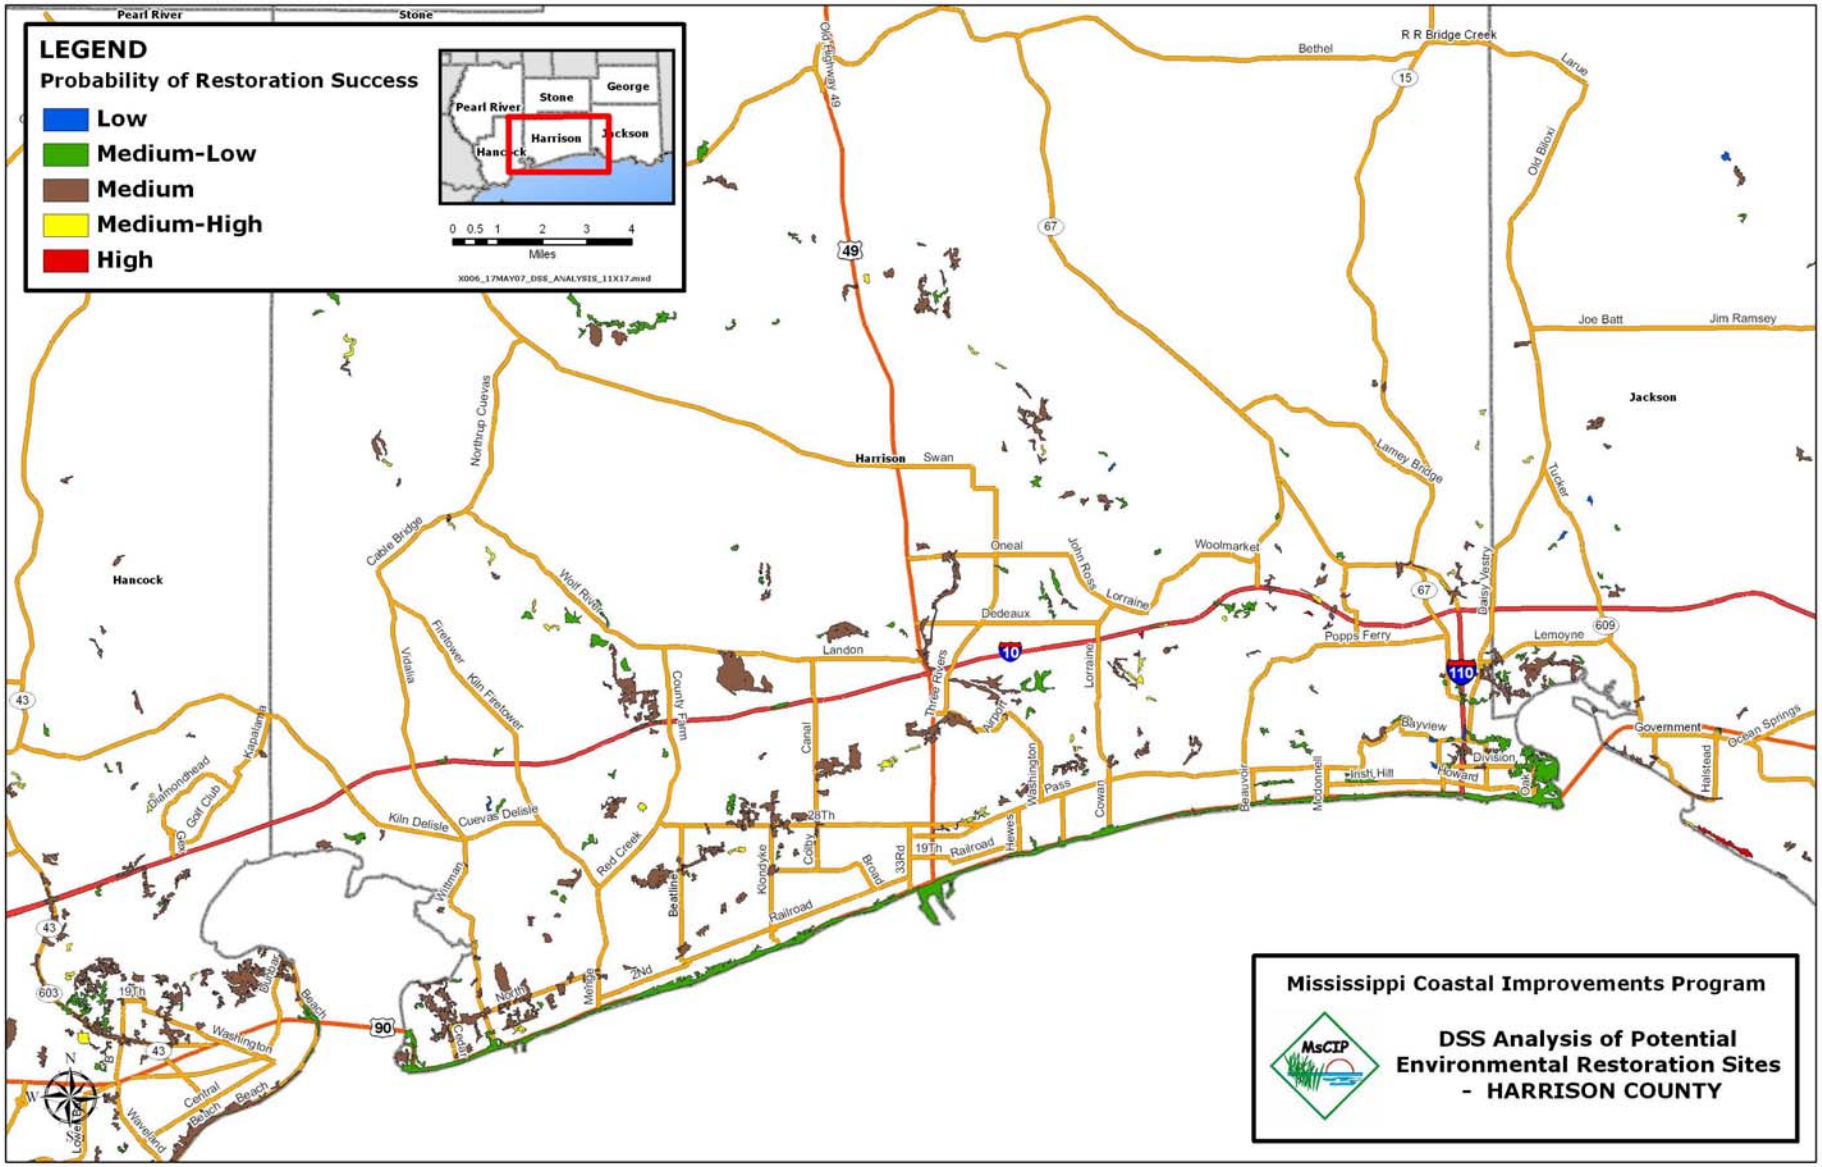
The methodology used for riparian and coastal wetlands is the HGM, developed by the USEPA, NOAA, Corps, and USFWS, calibrated for wetlands ecosystems found in coastal Mississippi, as used in many prior studies (Schaffer 2007). HGM is a science-based quantitative and replicable methodology that establishes functions ands values at a variety of sites and reference points that are then used to establish functional values for sites within the area be analyzed. HGM was applied at a landscape-level, using numerous reference sites in the area in the establishment of without-project conditions. The HGM model was used for the functional assessment of tidal fringe wetlands and wet pine savannahs within the study area.

Because HGM has not been calibrated for use in coastal maritime forest analysis in this area, an alternative methodology was used for the small number of beach, dune, and/or coastal maritime forest sites evaluated. The methodology chosen for this application was FHI. Functional production was quantified as an output that the fauna could potentially use. Functions evaluated in the matrix included substrates, habitat types, stabilization, and vegetation. In order to reduce subjectivity, the output was identified as an indirect or direct benefit. The “No Action” effort for a given project still has a FHI score even though there is no work proposed for the area. The FHI tables quantify expected biological output by linking biophysical benefits (termed functions) to specific restoration activities. The term biophysical, in this case, refers to the living and non-living components and processes of the ecosphere. Adding all of these outputs together from the table, and then multiplying by the acreage, provides an FHI score. A FHI model was used in the assessment of existing and future without-project conditions for coastal dune environments. This model is based on collaboration between resource agencies involved in past restoration projects.



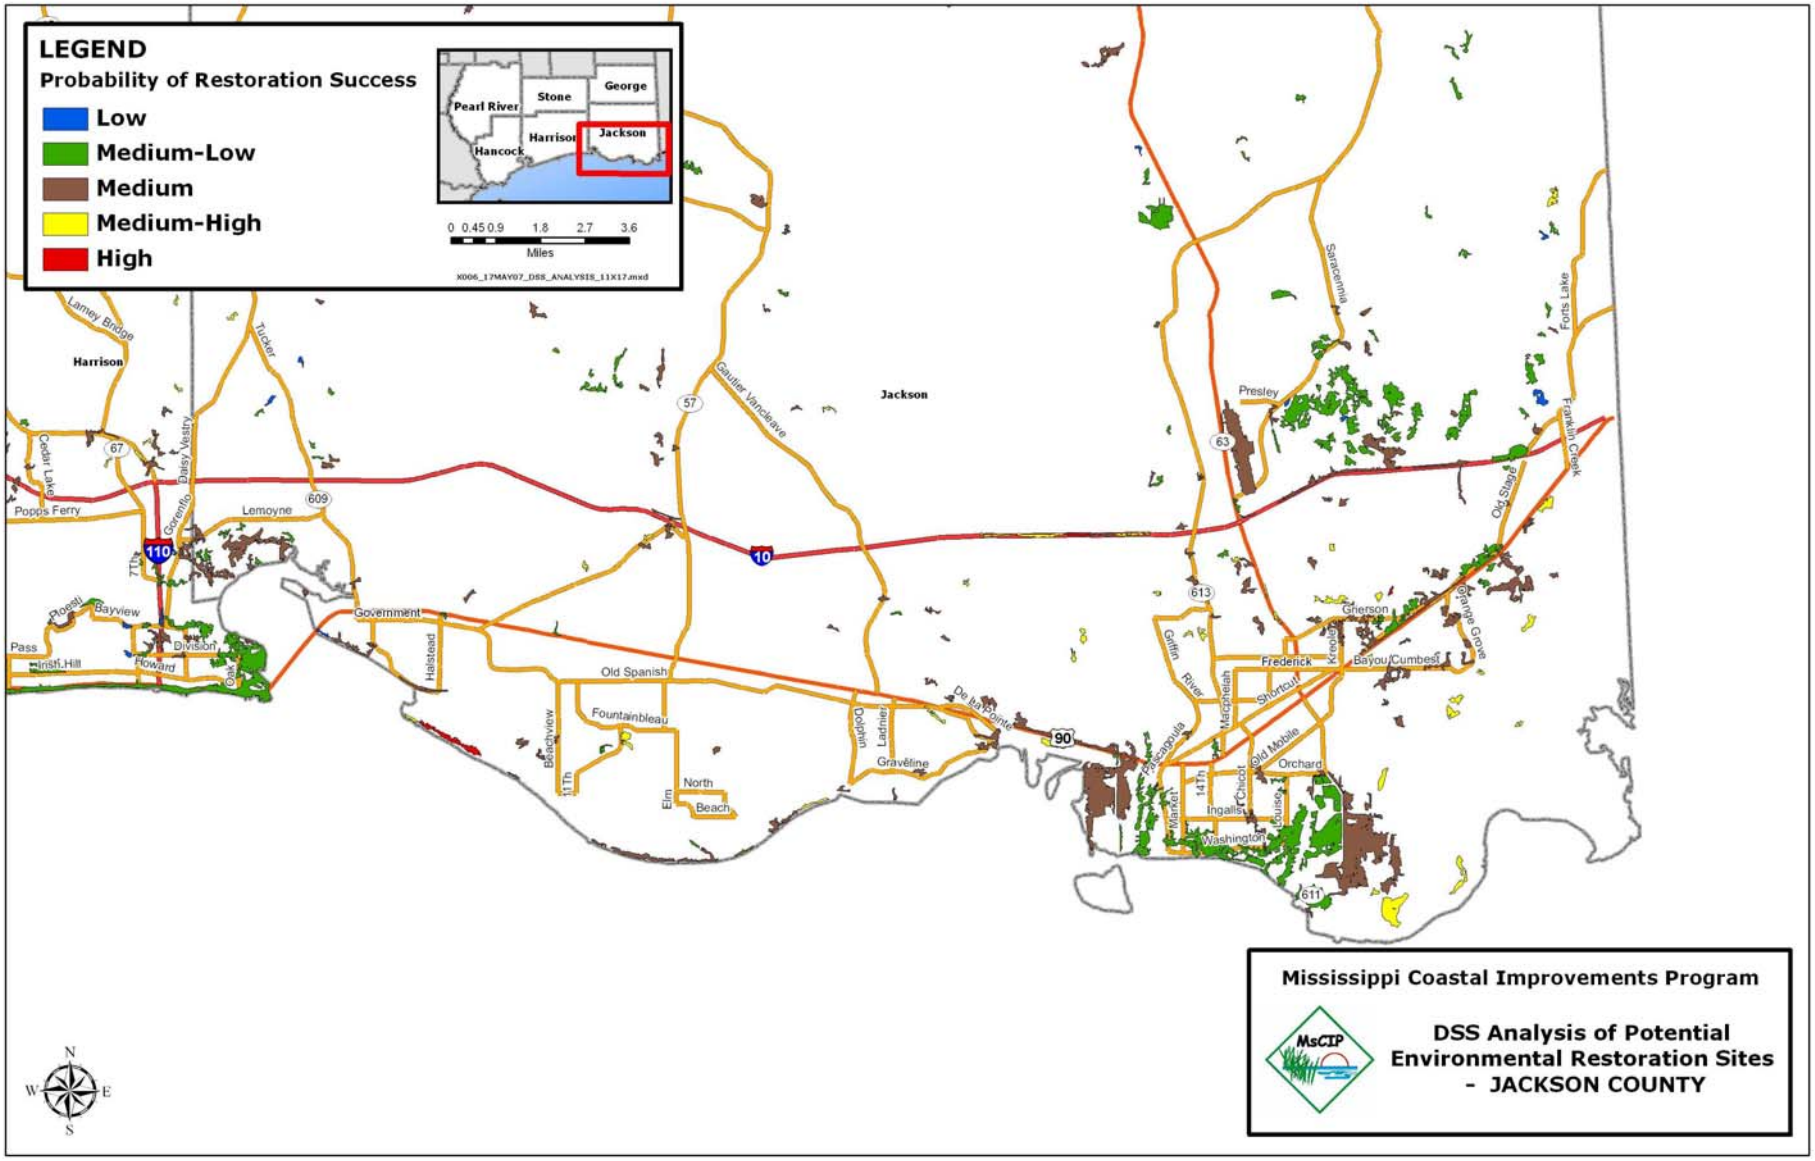
The SDSS tool allowed the Corps, Mobile District, working in cooperation with the USFWS and MDMR, to identify and prioritize potential wetland restoration areas throughout coastal Mississippi. A subset of potential restoration sites were identified by the SDSS tool and then ground-truthed by the MsCIP environmental team, including ERDC, Corps, MDMR, and USFWS. This interagency team allowed us to both confirm the accuracy of the SDSS results and to collect additional on-site information pertinent to restoration efforts. There are some major benefits in using the SDSS approach to wetland restoration. First, it allows for the relatively rapid assessment of the large number of restoration sites across the wide study area. Second, potential sites can be evaluated and restored in a watershed or landscape context, which allows us to comprehensively evaluate the overall natural system. This approach can maximize the benefits of wetland restoration, as opposed to simply restoring wetlands where convenient or where property is available. Essentially use of this SDSS tool allowed the MsCIP environmental PDT to assess the entire coastline as a holistic natural system; thus, the team was more effectively able to analyze needs in coastal Mississippi.

The SDSS effort resulted in the following products:



1. A ModelBuilder based SDSS tool, which can be subsequently edited and applied to other areas along coastal Mississippi in the future as funding becomes available;

2. Maps, such as aerial photography, topographic, soil layers, etc., depicting areas in the study region that have a high probability of being successfully restored into wetland functions that buffer and/or store stormwater, and provide suitable habitat for fish and wildlife; and



3. Photograph documentation and data sheets containing information on ground-truthed potential restoration sites.

1 **Figure 2. Hancock County Ecosystem Resources**

1 **Figure 3. Harrison County Ecosystem Resources**

1 **Figure 4. Jackson County Ecosystem Resources**

A FHI model was used in the assessment of existing and future without-project conditions for coastal maritime/beach-dune environments. This model is based on its use in the Corps' 2003 Section 204: Beneficial Use of Dredged Material at Deer Island, Harrison County, Mississippi Combined Planning and Design Report. The end product of the without-project conditions analysis was a set of functional scores for each problem area or site, which are presented in the Environmental Appendix.

A cost-effectiveness analysis was conducted for each of the measures and alternatives that were formulated for ecosystem restoration. The analyses followed the methodologies established in the Corps Institute for Water Resources (IWR) publications, Evaluation of Environmental Investment Procedures Manual, Interim: Cost-Effectiveness and Incremental Analyses, May 1995, IWR Report #95-R-1 and Cost Effectiveness Analysis for Environmental Measuring: Nine Easy Steps, October 1994, IWR Report 94-PS-2. The nine steps outlined in the cited IWR report have become the standard practice for identifying what are known as "Best Buy" ecosystem restoration measures, or those measures that yield the greatest 'bang for the buck' at various levels of output.

The IWR Measure model was developed based on these nine steps and is the preferred Corps model for the evaluation for ecosystem restoration measures. For the MsCIP Comprehensive Report and Integrated Programmatic EIS, Congressional Authority stated, "…but shall not perform an incremental benefit-cost analysis to identify the recommended project…." Following this authorization, only the first five steps of the nine easy steps, which are bolded below, were used in the IWR Plan evaluation, resulting in the identification of cost-effective plans for restoration purposes. The nine steps are:

- Formulation of combinations:
  Step 1 - Display Outputs and Costs
  Step 2 – Identify Combinable Management Measures
  Step 3 – Calculate Outputs and Costs

- Cost-Effective Analysis:
  Step 4 – Eliminate Economically Inefficient Solutions
  Step 5 – Eliminate Economically Ineffective Solutions

- Development of Incremental Cost Curve
  Step 6 – Calculate average costs
  Step 7 – Recalculate average costs for additional output

- Incremental Cost Analysis:
  Step 8 – Calculate incremental costs
  Step 9 – Compare successive outputs and incremental costs

3.3 Engineering Analyses

This section describes in very general terms the methods used to evaluate various elements and attributes of a "lines of defense concept". This concept involves multiple lines that include structural, environmental, and nonstructural features to accomplish the planning objectives. The lines are arranged in increasing levels of risk reduction from off-shore to in-shore up to the maximum possible intensity storm event that the team evaluated as possible for coastal Mississippi. This concept would utilize existing barriers such as the barrier islands, roadways, and railroad embankments as shown in Figure 5. Detailed descriptions of objectives, methods, and results are described in the Engineering Appendix.

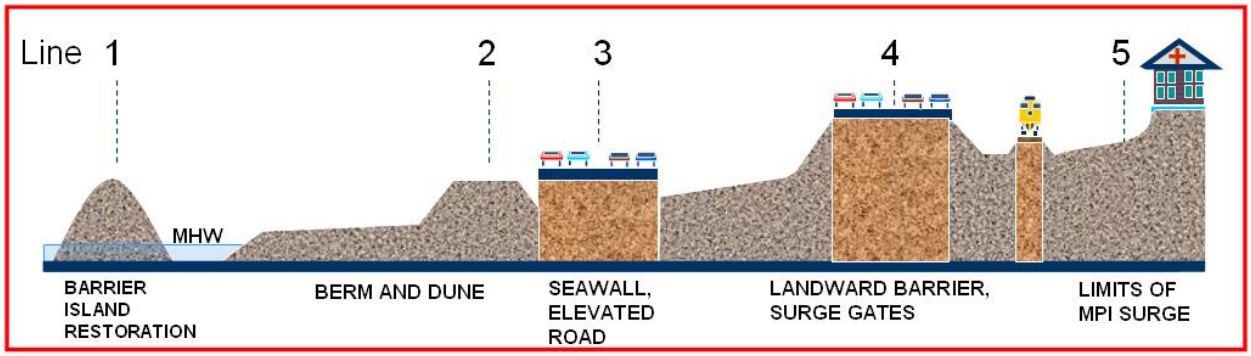


Figure 5 Lines of Defense Concept

3.3.1 Coastal Process Modeling

The purpose of this analysis is to evaluate the physical performance of the beach and dune system for anticipated future without-project and alternative with project conditions and to estimate the economic costs and benefits of each. The coastal processes modeling analysis employed the engineering-economic model Beach-fx (Gravens et al. 2007). Beach-fx relies on a shore response database to evaluate the beach and dune line of defense (line of defense two). The beach and dune analysis was evaluated considering the environmental forcing as characterized by plausible variants of the 71 historical tropical storm events that impacted the study area between 1886 and 2001.

The models applied to evaluate beach profile response to storms and project induced shoreline change are SBEACH (Larson and Kraus 1989) and GENESIS (Hanson and Kraus 1989). SBEACH is a numerical model for simulating storm-induced beach change that has been applied at numerous projects. SBEACH takes as input the storm time series (wave heights, wave periods, and total water elevations) and the initial profile definition, as well as other descriptors of the beach (e.g., grain size) and model parameters, and produces as output, the estimated beach profile at the end of the storm, as well as cross-shore profiles of erosion, maximum wave height, and total water elevation including wave setup. This information is extracted from the SBEACH output by post-processing routines and stored in the shore response database (SRD). The storm time series input is derived from a pre-computed surge response database developed by the Dredging Research Program (DRP) and the Wave Information Studies (WIS) database.

3.3.1.1 Hurricane Surge Modeling

A team of Corps of Engineers, FEMA, NOAA, private sector and academic researchers have been working toward the definition of a new system for estimating hurricane inundation probabilities. The findings and recommendations of this Risk Assessment Group are documented in a White Paper on Estimating Hurricane Inundation Probabilities (Resio 2007). The approach recommended by the group was a modified Joint Probability Method (JPM) referred to as the JPM with Optimal Sampling (JPM-OS). Generally, the approach involves wind and pressure field analysis and modeling; offshore and nearshore wave modeling, and storm surge modeling. For a full description, see Resio (2007). The general modeling approach is illustrated in Figure 6.

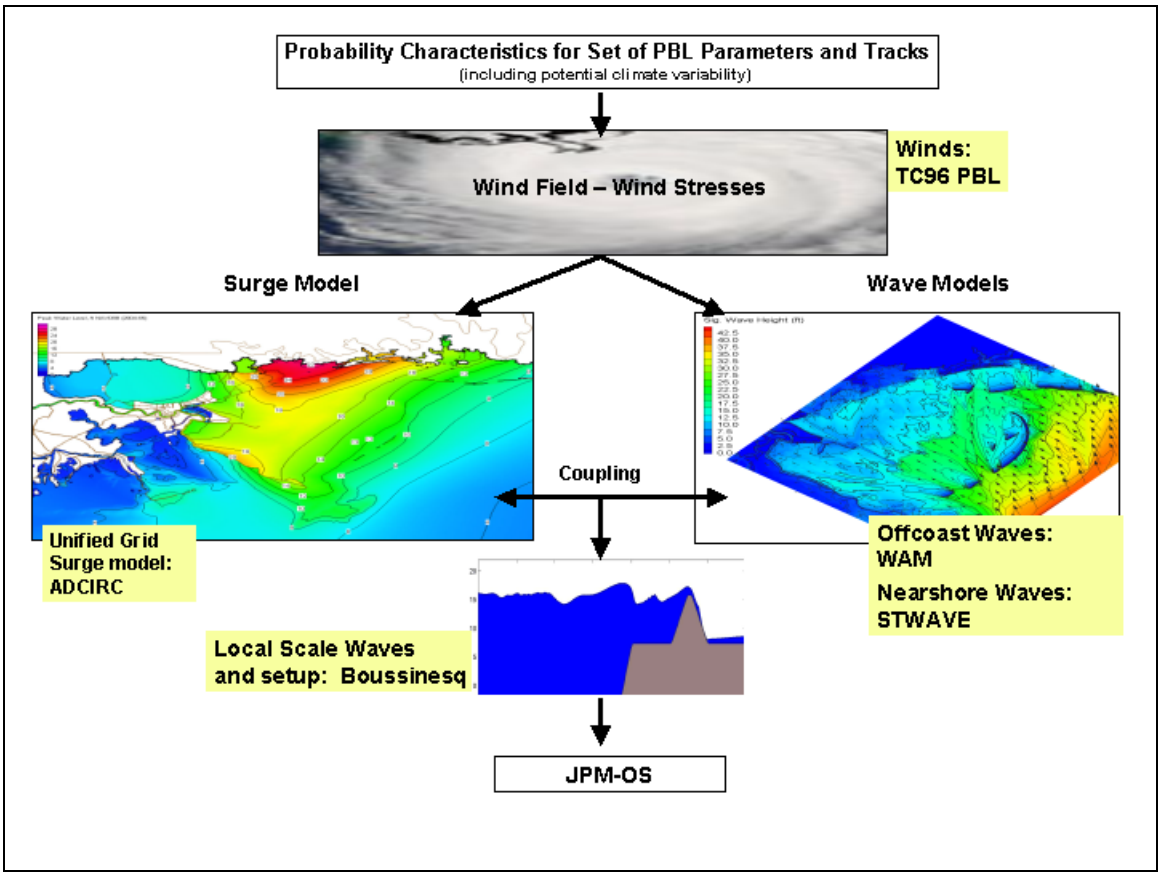

Figure 6. Diagram of modeling system for coastal inundation applications

Tropical cyclone surface wind and pressure fields were computed using the Planetary Boundary Layer Model, a.k.a. the TC-96 model. The wind and atmospheric wave fields were applied in (a) STWAVE to generate offshore and nearshore wave spectra and (b) ADCIRC generate bulk sea surge identities. These models were used iteratively to account for nearshore radiation stress transformation, and the resulting surge stage signature was modified for local shore feature effects based on limited application of the Boussinesq model COULWAVE.

Resulting storm surge surface envelopes were statistically sampled to derive surge stage-frequency relationships at a number of locations along the Mississippi Coastline. These relationships describe the stage for events with an annual chance of occurrence between 1 in 25 (or 4%) and 1 in 1000 (0.1%).

3.3.1.2 Stage-Frequency Curves

Stage-frequency curves are a foundational product for the present storm damage reduction design and analyses. The stage-frequency curves are the primary engineering inputs to economic flood damage analyses, and represent the static water surface elevation for non-structural flood damage reduction measures and levee crest height determination.

Stage-frequency curves describe the annual chance of occurrence of the surge still water elevation. The curves are composite curves, composed of both observed information (USACE tide gage observations at Gulfport, Biloxi, and Pascagoula) for more common events, and synthetic information (surge envelopes derived from statistical analysis of historic storm properties and imposition of those properties on the coastal environment through hydrodynamic wave and surge

models) for more rare events. The composite and synthetic portions of the curves were joined graphically. Given the focus on hurricane surge damage Curves were developed for 62 locations in the vicinity of the coastline, and another 18 locations in Mississippi Sound in the vicinity of the Barrier Islands. Stage frequency curves with uncertainty were developed for the without project condition; for the Line of Defense 3 condition; and for the Line of Defense 4 condition.

Uncertainty to plus and minus one standard deviation about the observed portion of the stage-frequency curves was developed using the method of order statistics. Uncertainty to one standard deviation about the synthetic portion of the stage frequency curve was based on a Gumbel distribution. Uncertainty limits were also joined graphically.

3.3.1.3 Flood Damage Reduction Analyses

The Hydrologic Engineering Center's Flood Damage Analysis (HEC-FDA) program uses risk and uncertainty analysis methods for evaluating flood damage and flood damage reduction alternatives. The program relies on hydrologic, hydraulic, and economic data input. Uncertainties in these data are input and used by the model for computing expected annual damages. Version 1.2.3b dated August 2007 was used. This is a customized version of the modeling platform which provides for input of user-specified stage-frequency uncertainty. The Engineering Appendix describes the model and it's application.

FDA models were developed for each coastal Mississippi county: Hancock, Harrison, and Jackson counties). Each county represents a planning unit, and each was further delineated into planning sub-units (PSU). There are ten PSU's in Hancock County, 19 in Harrison County, and 26 in Jackson County.

3.3.1.4 Levee Crest Elevation Determination

Levee heights were initially established based on interpretation of early hydrodynamic model output. A range of heights were conceptually designed and cost-height function was developed. The adequacy of a given levee height is related to social acceptability, cost-effectiveness, the desired level of protection, and local hydraulic and geotechnical performance requirements.

Hydraulic performance for purposes herein is predicated on limiting the average overtopping flow rate to a given threshold. The adopted threshold, based on application of limited mean estimates of coincident frequency significant wave height, peak period, and still water elevations, is 0.01 cubic feet per second per foot of levee. Wave heights, periods, and still water surface elevation frequency functions were provided by ERDC based on the hydrodynamic modeling program output. Such estimates are based on consultation with New Orleans District and are considered preliminary in accordance with draft levee certification regulations. Where required, wave properties are translated to the levee toe using the CEDAS program, which is also used to determine the required crest freeboard above the still water elevation for overtopping. Hydraulic performance evaluations are ongoing and are contained in Section 2.14 of the Engineering Appendix.

3.3.1.5 Regional Sediment Budget

This study evaluated the existing regional sediment transport magnitudes and directions for the Mississippi and Alabama barrier islands fronting Mississippi Sound and the mainland coast, including an analysis of historical long-term barrier island migration. A conceptual sediment budget was developed through a review of existing studies and is included in Section 2.12 of the Engineering Appendix. This budget formed the framework for the historical and calculated sediment budgets. Next, a historical sediment budget was developed through analysis of bathymetric and shoreline position change through time in consideration of engineering activities (navigation channel

construction, etc.) and significant storm events were also documented. A calculated sediment budget was developed based on STWAVE and GENESIS modeling for the Gulf and Bay shorelines of the barrier islands as well as the mainland coast. The final sediment budget was formulated from all these intermediate budgets.

3.3.1.6 Wetlands, Landscape Features, and Storm Surge

A literature review that documents studies that have measured and modeled storm surge elevations with the goal of understanding how landscape features and vegetation modify the surge elevation was conducted. A sensitivity study of a degraded and restored Biloxi marsh utilizing STWAVE was also performed.

3.3.1.7 Interior Drainage

Drainage on the interior of the ring levee would be collected at the levee and channeled to culverts placed in the levee at the locations shown above. The culverts would have flap gates on the seaward ends to prevent backflow when the water in Mississippi Sound is high. An additional closure gate would also be provided at every culvert in the levee for control in the event the flap gate malfunctions. A typical section is shown below in Figure 7.

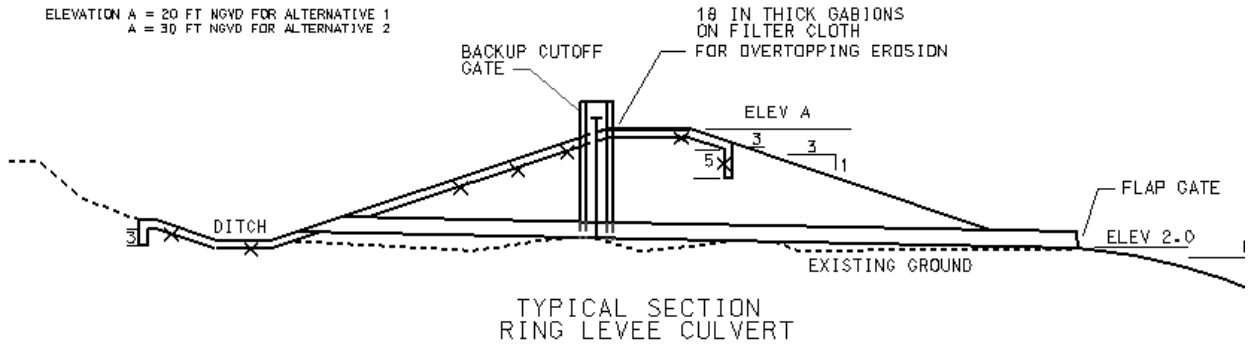

Figure 7. Typical Section at Culvert

In addition, pumps would be constructed near the outflow points to remove water from the interior during storm events occurring when the culverts were closed because of high water in the sound.

Flow within the levee interior was determined by subdividing the interior of the leveed areas into major sub-basins and computing flow for each sub-basin by USGS computer application WinTR55. The method incorporates soil type and land use to determine a run-off curve number. The variation in soil types, hydrologic soil groups, and major sub-basins was accounted for.

Peak flows for the 1-yr to 100-yr storms were computed. Levee culverts were then sized to evacuate the peak flow from a 25-year rain in accordance with practice for new construction in the area using Bentley CulvertMaster application. During periods of high water in Mississippi Sound, pumps would be required to evacuate rainfall. Pump sizes were determined for the peak flow resulting from a 10-yr rainfall based on an evaluation of rainfall observed during hurricane and tropical storm events as presented in two sources. The first is "Frequency and Areal Distributions of Tropical Storm Rainfall in the US Coastal Region on the Gulf of Mexico" US Dept of Commerce, Environmental Science Services Administration, ESSA Technical Report WB-7, Hugo V Goodyear, Office Hydrology, July 1968. The second is "National Hurricane Research Project Report No. 3, Rainfall Associated with Hurricanes (And Other Tropical Disturbances)", R.W. Schoner and S.

Molansky, 1956, Weather Bureau and Corps of Engineers. This decision was also based on coordination with the New Orleans District.

During some hurricane events, when the gates are shut, and rainfall exceeds the average 10-yr intensity over the basin, some ponding from rainfall will occur. Detailed modeling of all the interior sub-basins for all the areas was not possible for this report, therefore the exact extent of the ponding for extreme events is not precisely defined. The design rationale is based on the minimum facility concept, and economic tradeoffs between induced flooding and pumping provisions were not examined. Further studies will detail the requirement for the appropriate ponding areas, pump sizes, or buyouts in the affected areas.

3.3.1.8 Structural Damage Reduction - Engineering

Hurricanes are commonly recurring hazards for coastal Mississippi. The central Gulf coast region has one of the highest rates of occurrence in the U.S.. Development along the Mississippi coastline at relatively low elevations in many areas has created a landscape that is highly susceptible to storm damage. The two bays that divide the coastline of the three counties also aggravates the potential for inland flooding due to storm surge. The influence that landfall location for hurricanes may impart on storm surge is based on physical reasons and dictates why western Mississippi might register higher stages for a given hurricane than elsewhere along the Mississippi Coast. While the central coast of Mississippi has the highest topography, major hurricanes such as Camille in 1969 and Katrina in 2005 still produced surges that devastated this highly developed area. Approximately half of the coast of Mississippi including all of Harrison County has man-made beaches with high-value real estate immediately landward of the beaches. Essentially all of the structures facing the Sound were completely destroyed in Katrina.

Sea level rise and land surface subsidence have been taken into account as part of this study and the two together are reported as “relative sea level rise”, which accounts for both as a single value. Both factors play into the gradual rise in sea level compared to the land surface, over the period of analysis, or planning horizon.

The MSCIP Study incorporated many geotechnical considerations into the structural and environmental appendices of the report. All embankments in support of the various lines of defense were modeled for alignment footprint and quantities using Microstation’s CADD 3D and INROADS software. The basic design templates assumed side slopes of 1 vertical to 3 horizontal with a 15 foot crest for normal embankments and some greater than 75 feet in support of major roads. Access through the levees was provided by earthen ramps where the embankment heights were small relative to the existing ground and a small elevation gradient could be accommodated. Areas where the levee height differentials were too great or site conflicts prevented access ramps, then tunnels with closure gates were provided. All utility removals and reinstallations excavations were incorporated into the cost estimate for the individual feature. Materials to be used in the embankment and levee structures were assumed to be obtained from commercial sources with 10 miles of any given project. No formal geotechnical investigations were performed for this study. Geotechnical investigations will be performed for any project carried forward for feasibility design.

3.4 Non-structural Analysis

The nonstructural analysis for this study was performed as directed by Section 73 of the WRDA of 1974, and as prescribed in ER1105-2-100 and the Economic and Environmental Principles and Guidelines for Water and Related Land Resources Implementation Studies (March 1983). Section 73 specifically requires consideration of nonstructural alternatives in all flood damage reduction studies. These alternatives can be considered independently or in combination with other measures.

All nonstructural measures reduce flood damages without significantly altering the nature or extent of flooding. Damage reduction from nonstructural measures is accomplished by changing the use made of the floodplains, or by accommodating existing uses to the flood hazard. Examples are flood proofing, relocation of structures, flood warning and preparedness systems (including associated emergency measures), and regulation of floodplain uses.

The foundation of the technical analyses for nonstructural formulation was based upon five primary sources of data and associated models:

1) Tax assessor's databases from the three counties (Jackson, Harrison, and Hancock) that were further refined by the Mobile PDT,

2) FEMA databases for the National Flood Insurance Program that included Flood Insurance Rate Mapping, post Katrina damage assessments and GIS mapping, FEMA's model of the Advisory Base Flood Elevation mapping and associated topographic GIS layers,

3) The FEMA HAZUS model and databases for damageable structures in the project area,

4) Information and data gleaned from NOAA post-Katrina reports, and

5) Information on historic districts and buildings located in the project area from the National Park Service. Other databases from local communities and the US Census were used to describe local conditions, public buildings, housing resources, and current land use regulations (i.e. zoning, NFIP and building codes).

The nonstructural analysis was based in part upon research of proven nonstructural methods applied within coastal areas of the USA and determination of the relative surge inundation and wave hazards of the various coastal areas. Field observations of the damages to elevated and non-elevated structures and community facilities supported several aspects of the formulation process. FEMA data and flood zone mapping for the National Flood Insurance Program and post-Katrina damage reports supplied information on the location and extent of high-hazard flood zones that defined the division between areas suitable (safe) for floodproofing by elevation and those areas only suitable for permanent acquisition.

Several established computer programs were used to collect and analyze the parcel data and GIS mapping from the above sources including Microsoft Excel, Microsoft Access, and ESRI ArcMap Versions 9.1 and 9.2. These computer programs were used to create the database spreadsheets that supported the formulation of the various nonstructural measures and plans as well as the basis for the nonstructural cost models. The ArcMap programs were used to create the nonstructural graphic plans for the various measures and combinations of measures displayed in the Nonstructural Appendix.

The formulation and analysis of applicable nonstructural measures was based upon the Corps' Engineering Regulation 1105-2-100, The Corps Planning Manual (IWR Report 96-R-21), applicable sections of Corps regulations regarding real estate acquisitions (ER 405-1-12 and CFR, Title 49, Part 24) and public buildings and facilities relocations (EFARS Appendix Q - Relocations, Alterations, Vacations and Abandonments October 1984), provisions of the Uniform Act (PL 91-646) and various floodproofing regulations from the FEMA National Flood Insurance Program as well as applicable sections of the Mississippi State Code (Title 17-1-17) regarding local land use, zoning and regulation capabilities.

3.5 Economic Analysis

This section describes the methodology for the evaluation of economic impacts of potential solutions for the Mississippi Gulf Coast under the Mississippi Coastal Improvements Program (MsCIP) Comprehensive Report. It is intended to be an outline of the process used to determine the economic impacts that are fully detailed throughout this report and in the Economic Appendix. The methodology was developed to seamlessly fit into the six step planning process and current Corps guidance. The six step planning process, as defined by the Engineering Regulation (ER) 1105-2-100; Economic and Environmental Principles and Guidelines for Water and Related Land Resources Implementation Studies (U.S. Water Resources Council 1983), referred to as the P&G, is:

1. Identify Problems and Opportunities
2. Inventory and Forecast Conditions
3. Develop Alternatives
4. Evaluate Alternatives
5. Compare Alternatives
6. Select the Recommended Plan

The Mississippi Gulf Coast is a complex system that is made up of a diverse blend of ecological and human habitats. Given those complexities, a fluid and flexible process was needed to evaluate and aggregate the benefits of potential measures and measures. The process incorporates data collection, forecasting techniques, scenario planning, cost effective evaluation using state of the art modeling techniques, and the communication of both benefits and risks associated with potential measures and measures. Figure 8 outlines the process used for this analysis.

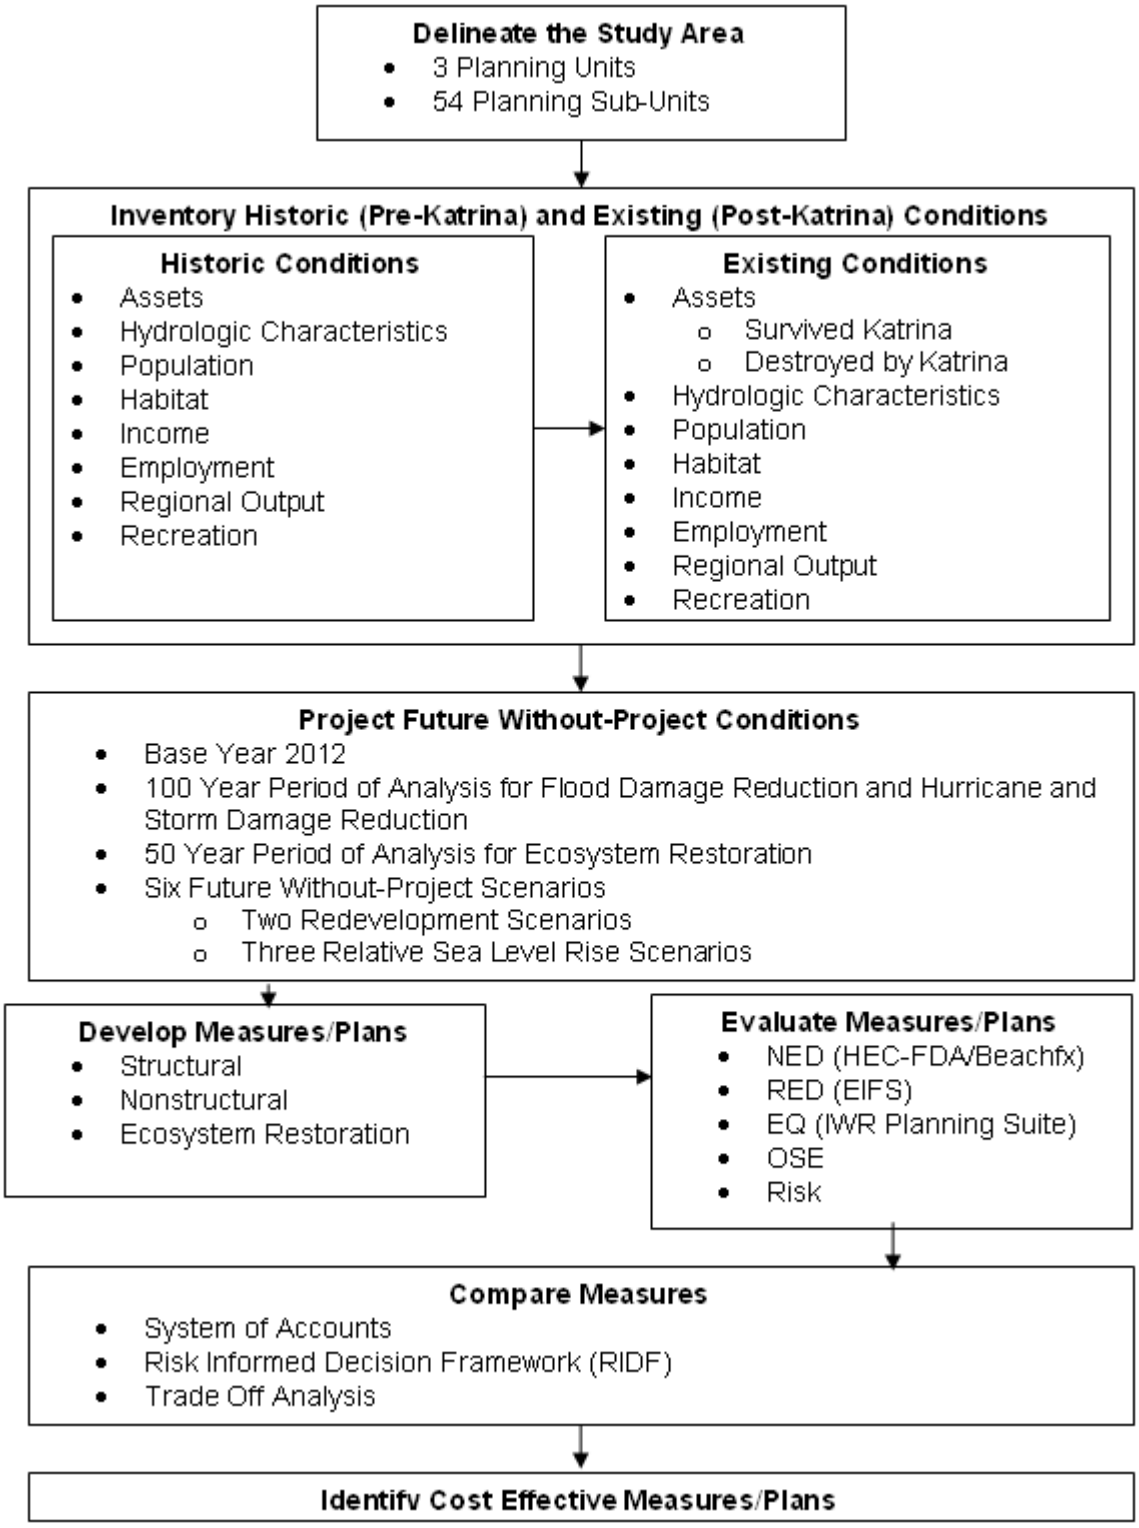

Figure 8. Overview of Economic Methodology

The first step in the process was to delineate the study area. The overarching study area, as defined by Congress, is the three coastal counties in Mississippi; Hancock, Harrison and Jackson from west to east respectively. For purposes of system wide evaluation and aggregating benefits, the study

area was divided into four planning zones, three planning units, and fifty-four sub-planning units. These are described in more detail in the following section.

Once the planning zones, planning units, and planning sub-units were identified, the next step was inventorying the economic, social, and environmental characteristics of the area. Data from Local, State, and Federal government agencies was utilized to determine the Historic (Pre-Hurricane Katrina) Condition, including data from the U.S. Census Bureau, the Federal Emergency Management Agency (FEMA), U.S. Fish and Wildlife, the Mississippi Emergency Management Agency (MEMA), the Mississippi Governor's Recovery Office, County Tax Assessors, previously conducted Corps of Engineers studies conducted in the area, and other valuable data sources. Historic data included economic structures (structures, content, and critical infrastructure), social and regional indicators (population, income, and employment), topographic and hydrologic characteristics, acreage of habitat, and etc.

With the historic data serving as a foundation, the next step was to determine the impacts of surge inundation from Hurricane Katrina. The team developed an inventorying methodology that was a combination of sampling and field verification. PDT members drove every street within the fifty-four planning sub-units over the course of four months from June to October, 2006, for purposes of determining the existing (Post-Hurricane Katrina) conditions and characteristics of structures. The findings of this work were put into a structure database that included over 200,000 tax parcels, 138,000 of which contained structures. Hydrologic programming was used to evaluate the surge inundation of each planning sub-unit and a combination of ESRI's ArcMap 9.1 Geographical Information System (GIS) data and ground truthing was used for habitat evaluation.

Six future with-out project scenarios were developed, based on the existing condition characteristics, for the evaluation of future without-project conditions. The six scenarios were evaluated over a 100-year period of analysis from the base year 2012 (2012-2111) and using the FY07 federal discount rate of four-and-seven-eighths (4.875) percent. The six future scenarios include two redevelopment scenarios (residential and mixed-residential and commercial) and three relative sea level rise scenarios (existing sea level, moderate relative sea level rise, and high relative sea level rise) for a total of six different future scenarios. Scenario one is a residential redevelopment with no relative sea level rise over the period of analysis, scenario two is a mixed residential and commercial redevelopment with no relative sea level rise, scenario three is a residential redevelopment with a maximum relative sea level rise depending on location of 2.0-feet over the period of analysis, scenario four is a mixed residential and commercial redevelopment and a maximum relative sea level rise of a 2.0-foot, scenario five is a residential redevelopment with a relative sea level rise depending on location of 3.4-feet, and scenario six is a mixed residential and commercial redevelopment with a maximum relative sea level rise depending on location of 3.4-feet. The detailed evaluation of these scenarios is outlined in the Economics Appendix, and a technical description of the calculation of relative sea level can be found in the Engineering Appendix.

The next step, identified as step three in the planning process, was to develop measures that relate to the planning objectives for this study. A measure is something that can be implemented to directly address a problem within the study area. Some examples of measures include levees and acquisitions for flood damage reduction, beach and dune construction for flood damage reduction and ecosystem restoration, excavation and planting of native species for ecosystem restoration. These measures can be stand alone or may be able to be combined like a system.

For the Mississippi Coastal Improvements Program (MsCIP) Comprehensive Plan Report, multiple measures were developed under structural, nonstructural, and ecosystem restoration categories. The project delivery team applied a screening process based on engineering, environmental, and economic feasibility to narrow the list of viable measures.

The result of the screening was a list of measures that were fully evaluated as compared to the future without-project conditions. These measures were evaluated using the four systems of accounts, outlined in ER 1105-2-100, which include National Economic Development (NED) benefits, Regional Economic Development (RED) benefits, Environmental Quality benefits, and Other Social Effects (OSE). Evaluations of the various metrics that make up these four accounts were conducted using multiple economic programs, expert opinion, and other sources where available. The main economic programs used for the evaluation of measures include the Corps of Engineers Flood Inventory Tool (CEFIT), the Hydrologic Engineering Center-Flood Damage Analysis (HEC-FDA) program, the Beach-fx program, the Institute for Water Resources (IWR) Planning Suite, and the Economic Impact Forecasting System (EIFS). Outputs from these programs were carried forward for the comparison of the measures.

The final two steps of the process include a comparison of measures/plans and the identification of cost effective plans. A comparison of the evaluated measures was conducted using the System of Accounts (SOA) table and the RIDF process developed specifically for the MsCIP and LaCPR studies.

3.6 Geographic Information Systems (GIS) Approach and Analyses

During the MsCIP Comprehensive Study, several Geographic Information System (GIS) software components were used. The GIS software used was created by ESRI and include: ArcGIS, ArcIMS, ArcReader, ArcGlobe, and ArcSDE. ArcGIS is used for analysis of geospatial data; this software allows the user to overlay data and perform analysis on the data. ArcIMS is used in displaying GIS data on the internet; this software allows users to view and query data without having to purchase software or need training to run the software. ArcReader is a GIS component that allows users to look at data on their local computers without having to purchase software and requires very little training. ArcGlobe is the GIS component that allows users to view data in 3D and is great to use when dealing with depths and heights. ArcSDE is the GIS component that is used to store and organize geospatial data.

3.7 Real Estate Analyses

Real estate costs are an important part of evaluating and comparing different measures to solve a problem. The real estate analysis includes descriptions of the minimum real estate requirements for different measures, estates to be acquired for the alternatives, Land costs to include Easements, Rights-of-way, Relocations and Disposal or borrow areas (LERRD's), and schedules for real estate activities. The real estate analysis was conducted in accordance with Corps' Guidance from Engineer Regulations 405-1-12, and from the Code of Federal Regulations, Title 49, Part 24. Other supporting guidance can be found in the attached Real Estate Appendix.

The real estate analysis for this study required a search of the local public records at local tax and county clerk's offices, to obtain data about owners and the types of properties that would be impacted by potential measures. The analysis includes the proposed acquisition of any land rights in privately owned lands that would be required for the building of a structure like a levee, and any other real estate requirements appropriate for the project construction. The acquisition of land rights may be either a partial or complete purchase of a parcel or tract of land, and in an easement or fee simple interest. Relocation assistance for landowners or tenants when structures are impacted is also included in the analysis. For the nonstructural buyout measures, fee simple purchase of lands and structures along with relocation assistance to displaced persons is recommended. Any such

acquisitions of real estate interests and/or relocation assistance for displaced persons are governed by Public Law 91-646.

An assessment was also made of which public facilities would need to be relocated for each measure, including roads, pipelines, utilities, and bridges. The Real Estate Appendix includes information as to the costs and land requirements whether the Government or the local Sponsor would be responsible for the relocation. More detailed investigations of items such as land for borrow areas, pipeline routes, staging areas, etc., will be conducted in a future feasibility study, or studies, if authorized by Congress.

Structural measures, as well as potential Nonstructural buy-out and Ecosystem Restoration sites, all have real estate requirements. Although some measures overlap, each could be constructed as a stand-alone project, and requires a separate real estate cost estimate. The total estimated cost includes land and any associated improvements, relocation payments, and administrative costs to acquire lands and provide relocation assistance services.

The Project Delivery Team (PDT) obtained tax databases for 2005 from the tax assessors' offices in Jackson, Harrison, and Hancock Counties. The team linked this information with GIS “footprints” of the measures to aid in sorting and querying of large amounts of data. These queries were imported into spreadsheets for use by economics, cost engineering, and environmental team members.

Due to the magnitude of the study involving evaluation of approximately 75,000 parcels, a number of assumptions were made in compiling the Real Estate costs. The average number of potentially impacted parcels for the individual interior barrier measures varied anywhere from 320 to over 1,700 parcels. The process originally began by looking at what percentage of each individual parcel might be impacted by the construction of a measure. As changes occurred and more measures were added, it became necessary to discontinue the parcel by parcel analysis and instead make determinations to estimate subsequent real estate requirements based on a percentage factor. Assumptions were also made for when an entire parcel needed to be acquired, and what percentage of structures on a parcel would potentially be impacted by a given measure.

While costs are based on assessed values from the 2005 tax year, an appraiser completed a market study using approximately 135 comparable sales from the three coastal counties. All of the sales used occurred in the first quarter of 2007. From these sales an "adjustment factor" for each county was established. It was found that post Katrina real estate values were approximately double the pre-Katrina values, and the adjustment factors for each county ranged from 1.75 - 2.50 percent. For planning purposes, this adjustment factor was used to bring the assessed values more in line with 2007 "market values".

A Real Estate Supplement (RES) will be prepared for each authorized component once the real estate requirements have been sufficiently identified during a Pre-construction, Engineering, and Design phase (PED). The RES will provide updated information as to final real estate requirements for a particular component and will include updated real estate values and costs. A Real Estate Relocation Plan for displaced individuals and businesses would also be prepared during PED. The Relocation Plan will investigate the availability of replacement housing within a specified radius and any unique or unusual problems that should be considered.

3.8 Costs Estimating Analysis

Rough order magnitude cost estimates have been developed for each of the tentatively selected plan components and comparative alternatives. All cost estimates for a specific plan component/alternative concept have been developed to the same level of detail and include the same level of uncertainty with regard to the precision of the estimate. As discussed below some

estimates are considered to be more advanced in that a selected design may have been available to use in developing the estimate.

In general the cost estimates for structural options are based on conceptual designs. To proceed with initial cost estimates, the structural options were conceptually designed to the selected elevations (i.e. 20 feet, 30 feet, or 40 feet) as described in previous paragraphs. These initial elevations selected for each component of the lines of defense are assumed to bracket a wide range of potential storms with corresponding surge elevations. Using these preliminary designs, rough order of magnitude cost estimates were completed for each of the structural options. These cost estimates can used to develop cost curves for future use to estimate costs after final design elevations are selected. Also, these cost curves, can be used in future studies to select varied levels of risk reduction based on risk assessments as well as taking into account future estimates of sea level rise. Cost estimates include not only the construction costs, but also any real estate and/or environmental costs as appropriate. In some cases the costs of environmental mitigation have been assumed to equal the cost of purchase of lands in mitigation banks. Additional detail is necessary before fully developed costs estimates can be developed. As discussed below, the team has included in the estimate a factor for uncertainity with regards to a number of factors (contingency percentages). Costs for plans and specifications have been included where applicable.

Costs for all the environmental restoration options are also estimated at the same rough order of magnitude type estimate, however unlike the structural options, each option had a selected design and no cost curves are developed. Costs for environmental restoration features are based to the maximum extent on prior efforts by the Mobile District in the Mississippi area (i.e. dredging costs for sand placement on barrier islands; costs for acquiring and installing specific vegetation species). Costs for plans and specifications, monitoring and any additional studies have been included where applicable.

Non-structural costs were generated from spreadsheet summaries of the tens of thousands of real estate parcels assigned to the 54 economic reaches based on available data from county tax data bases. All non-real estate contract costs (demolition or flood proofing) for inclusion into these spreadsheets were completed by cost estimators familiar with these activities and acquisition costs were provided by real estate specialists.

A specific analysis of the uncertainties of the cost estimates is being performed to best define the risks associated with the level of cost estimating used for this effort.

3.8.1 Uncertainty as Related to Construction Costs

Even though a Cost Risk Analysis was not developed for the total project cost estimate, some uncertainties were identified and addressed in developing the Construction Contingency. Such uncertainties identified included (a) lack of geotechnical information, (b) physical size and complexity of project, (c) a number of features of the project not being of conventional design, (d) contract requirements, (e) economy shifts, market forecast, (f) quantities not available; assumptions made based on historical information, (g) exclusion of hazardous, toxic, and radiological waste assessments and escalation cost, and (h) no detailed project scheduling.

Contingency in the construction cost estimates represents an allowance for elements within the project scope that are not included in the detailed estimate. This contingency allowance provides a level of confidence that the cost estimate will not overrun due to unpredicted events. Contingency is not intended to cover such factors as estimating allowances, change in scope, inaccurate projections of inflations, unanticipated regulatory standards, and other external factors (bad weather, strikes, labor disputes).

Based on review of identified uncertainties and the project delivery team's (PDT) judgment, the assumed **risk level** is considered higher than normal. Therefore, a Contingency of 25% was used throughout the cost estimate. Even though ER 110-2-1302 identifies Contingencies at 20% for projects greater than $10,000,000 for recon/feasibility phase, it was determined and agreed upon by the PDT that a higher rate should be used primarily due to higher risk than normal, degree of confidence lower than normal, and many features of the project not being of conventional design.

3.8.2 Uncertainty Relating to the Delineation of the High-hazard Areas for Real Estate Acquisitions

Numerous factors contribute to the uncertainty in Real Estate cost estimates. Estimates were made based on proposed project footprints for which plans and specifications are not finalized. Consequently there may be some variance, either higher or lower, in the total number of parcels impacted for a particular option. It is likely that a parcel which may be considered to be partially impacted by project construction could in fact be avoided when plans and specifications are completed. In addition, the real estate land cost is based on tax values with an adjustment factor for 2007 applied to bring the valuations of parcels in line with market values. Additional adjustments may be required to remain current with market conditions and values as project construction is scheduled.

There may also be a variance in the number of structures projected as being impacted since the footprint of actual structures was not available during the data analysis. Assumptions were made based on the "percentage of impact" to the parcel where a structure was shown in the tax data base. The county data bases, appeared to have a mix of pre-storm and post-storm data which mostly affected structure values. If the tax data included a structure value, an assumption was made that a structure is in existence. However, a site inspection is necessary to confirm the actual existence of a structure. Similarly, a parcel assumed to be vacant as per tax information could have a structure at the actual time of acquisition.

The number of relocations under P.L. 91-646 that are projected relates directly to the number impacted structures, and will increase or decrease proportionately with any increase or reduction in the number of structures impacted. An average cost was used across the project for a "relocation" payment with no distinction being made between relocation of an individual or business. Before implementation of acquisition, a relocation plan will need to be completed to gather more specific information and to prepare a more refined cost estimate.

Administrative costs used in the estimate are based on historical costs per tract for other projects. Although none have been as large as the MsCIP, they are thought to be a sound basis for this project. A contingency of 25% was used throughout for each cost estimate prepared.

3.8.3 Uncertainty as Related to Non-structural Costs

The uncertainties related to the delineation of the high-hazard zones would affect the number of tax parcels selected for permanent acquisition versus floodproofing by elevation. In all cases, parcels lying along that line of demarcation between the two measures would be either permanent acquisition or floodproofing by elevation, therefore any differences in cost could be expressed as the average cost difference between the two measures. In the formulation of the accelerated High Hazard Area Risk Reduction Plan the average homeowner payment for acquisition was calculated to be $143,000. The average cost estimate to raise an existing structure up to 6 feet was $140,000 – a difference of $3,000 between the two measures for any structure along the demarcation line.

The differences in the number of parcels allocated to one or the other of the two measures would affect the relative amounts of cost allocated between the project accounts. Since the lines

delineating the various zones may have not exactly matched the parcel boundaries, there is some inherent inaccuracy in the accumulation of the affected parcels by the GIS database in one or the other of the two categories of measures included in the plan.

The uncertainty surrounding the delineation of the high-hazard areas along the Mississippi coast is based upon three primary components: 1) the accuracy of the FEMA geographic information system (GIS) layer that delineated the VE Zone (Velocity Elevation Zone) on the Flood Insurance Rate Maps for the three counties and municipal areas along the coast, 2) the accuracy of the GIS layer delineated by FEMA in their post-Katrina report regarding the catastrophic damage zone where damages to insured structures exceeded 50%, and 3) the accuracy of a GIS-generated polygon depicting a 800-foot wide buffer zone in Jackson County that mimicked the damage areas observed in Hancock and Harrison counties.

The GIS layers used in the Nonstructural Appendix to delineate the VE and catastrophic zones were taken from FEMA published data. Considering the scales used on FEMA National Flood Insurance Program mapping and the dates of the flood insurance rate maps from which the GIS layers are taken (1970's) it's likely that there are inherent inaccuracies in the GIS layers. Any inaccuracies that may have been inherent in that data have been carried into the Corps document. The construction of the 800-foot wide buffer area was generated and whatever inaccuracies are imbedded in that layer are also within the report database.

3.9 Communication and Collaboration

Collaborative planning requires that the Corps move beyond the Corps interest and embrace solutions that reflect the full range of the national Federal interest. In an effort to fully embrace this, concept steps have been taken to involve all applicable state and Federal agencies in the development of the various measures being considered. The USFWS and NPS have assigned specific individuals to be on staff at the District as they participate on the PDT. Other agencies have identified specific individuals to represent their agencies on all team efforts. Further, the environmental PDT has been communicating on-going effort to the resource agencies. Measures that have been developed relate to activities that cross all boundaries of the Federal government. In particular, plans for the systematic restoration of the Mississippi barrier islands have been developed jointly by the NPS, USGS, NOAA, EPA and the Corps. Collaboration with the State of Mississippi is a critical building block of the MsCIP as we move forward with the long-term restoration of the coast. Elements of this collaboration including sharing personnel and data have resulted in the development of a comprehensive restoration strategy.

Communication among all the stakeholders has been a critical element of the MsCIP. From the inception, the importance of communication is evident with the hiring of a specialty firm to assist in the development of the stakeholder base and the dissemination of information. Group Solutions Inc. has employed a number of innovative techniques to assist in obtaining participation from the largest number of stakeholders possible. The MsCIP communication plan includes the use of public workshops and meetings, meetings with special interest groups including NGOs, web based meetings, and extensive use of the internet to facilitate communication. As a result of the extent of the damage from the hurricanes, a large number of stakeholders have been displaced and every effort has been undertaken to reach these individuals as well as those currently residing along the coast. Although a large amount of effort has been taken to reach the stakeholders (over 30 meetings since April 2006), we are still not satisfied with the participation and will continue to take additional steps as the comprehensive plan develops.

3.9.1 Regional Sediment Management (RSM)

Regional Sediment Management uses the understanding of sediment dynamics (inputs, outputs, movement) to manage sediment resources towards implementing environmental restoration, conservation, and preservation while reducing coastal erosion, storm damages, and associated costs of sediment management. The MsCIP study team is building on RSM relationships, technology, data, and tools; likewise, the RSM program is benefiting from the extension of these relationships, technology, data and tools as well as lessons learned through MSCIP. Prior to the MsCIP project, data and information were lacking along coastal Mississippi. The MsCIP project is providing valuable information and data, and is improving our understanding of the coastal processes, which occur along the Mississippi mainland shoreline as well as the barrier islands. Additionally, MsCIP project's coordination and relationships developed with other Federal agencies, sponsors, and stakeholders will enhance the RSM programs ability to coordinate and implement future RSM strategies in coastal Mississippi.

Formulation of measures and alternatives fully considered the opportunities of applying RSM. Measures formulated consistently considered the beneficial uses of sediment in the larger ecosystem, as well as ways by which sediment delivery or re-allocation could be enhanced to areas of greatest need. This objective was carried through the formulation, evaluation, screening, and selection process.

The State of Mississippi as part of Gulf of Mexico Alliance has acknowledged that sediment resources are integral to accomplishing many restoration initiatives. It is also recognized that there is a need for a better understanding of regional sediment systems and processes to inform decisions about projects and actions that use or affect sediment resources. Mississippi is actively involved in the development of a Gulf Regional Sediment Management Master Plan as an implementation action for the Gulf Alliance Conservation and Restoration Workgroup. The regional sediment management plan will also help link sources of sediment with sediment needs, provide a basis for assessing competing needs for sediment, and foster more cost effective sediment management.

3.9.2 Public and Agency Involvement in the Planning Process

The Corps' 6-step planning process is a structured approach to problem solving that provides a rational framework for sound decision making. The 6 steps consists of: identifying problems and opportunities; inventorying and forecasting conditions; formulating alternative plans; evaluating alternative plans; comparing alternative plans; and selecting a plan. The MsCIP team has made every effort to involve the public and agencies throughout the entire Interim and Comprehensive Plan development. Immediately following Hurricane Katrina, members of the MsCIP team were openly communicating with state, federal, and local agencies regarding their concerns, obstacles, hurricane-related problems, needs, and opportunities. Agencies, educational institutions, and interested individuals have been contacted via phone, e-mail, or public notice, to solicit input, ideas, and constraints to the plan formulation process. A website was developed and maintained as a way of disseminating information and receiving public comments regarding potential issues and their concerns. Over 60 Federal, State and local government agency representatives and other community leaders from business and industry gathered in Biloxi on April 7, 2006 to identify early needs, opportunities and recommendations for the MsCIP process. Many other public and agency meetings have been held in Harrison, Jackson and Hancock Counties to examine a broad range of potential coastal protection options and solicit input on designing comprehensive improvements. Comments received from these meetings have led the team to revise some of the initial proposed measures. Existing and future conditions were identified and projected in coastal Mississippi by Corps, MDMR, USFWS, and the NPS members. On May 7, 2007, the MsCIP team held a public workshop to present additional environmental, structural and non-structural measures. Input provided from these meetings was used during further formulation of the comprehensive plan.

3.9.2.1 Initial Coordination by Mobile District Team

The hurricanes of 2005 caused numerous deaths and untold injuries to local residents and visitors to the area, extensive damage to environmental resources, homes, businesses and industries. Soon after Hurricane Katrina struck coastal Mississippi, the Mobile District made and received contact with local government officials, agencies, and the public regarding the impacts of the storm and conditions on the coast. This interaction was encouraged by the existing working relationships established during the normal water resource activities conducted by the Mobile District and the state and local governments. After the MsCIP authorization, Mobile District multi-disciplined project teams went to each coastal Mississippi county and municipal area to assess damages and needs first hand identifying needs and formulating ideas and opportunities.

3.9.3 Public and Agency Involvement Process

The MsCIP team places a high value on public and agency involvement during development of the Interim and Comprehensive Plans. Participation from Federal and state agencies, local governments, and stakeholders was obtained through an on-going and engaging series of public scoping meetings, public input meetings, agency and stakeholder meetings, web-casts, on-line auditoriums, Federal principals group, vertical teams, regional coordination meetings, in-house USFWS and NPS personnel, MDMR personnel, non-structural road shows, on-site meetings and multi-participant plan formulation.

3.9.4 Public Input and Review of Planning Options: Round One

Planning solutions to water resource problems is not an activity just for engineers and scientists. It also involves homeowners, businesses, environmental advocates, interest groups, and other members of the public as well as people from Federal, State, regional and local agencies. Citizens have the right to participate meaningfully in public decision making processes, and to be informed about the bases for those decisions. In addition, public participation will undoubtedly lead to better decisions. The wisdom needed to solve complex problems is not limited to the technical experts in public agencies. Early and continuing participation by a diversity of interests, including project sponsors, customers, partners and other stakeholders, can provide essential information and insights. Public participation also increases confidence in the planning process and acceptance of its resulting decisions. The following sections show how the public was involved early and often during the MsCIP planning process.

3.9.4.1 Regional Coordination Workshop

A highly interactive Regional Coordination Workshop was held in Biloxi, MS, on April 7, 2006 for a group of state, municipal, county, NGOs, and agency officials. Approximately 200 participants were invited to attend the workshop through letters, e-mails and phone contacts. Approximately 75 individuals participated representing a spectrum of participant groups invited. Participants were asked to provide the Corps guiding principles for MsCIP direction and specific projects that should be included within the two plans (i.e. Interim and Comprehensive) for Congress. Over a hundred ideas were generated at the workshop. The ideas ranged from small local projects to coastal-wide submissions. The MsCIP Team reviewed these ideas or potential projects for consideration as near-term projects in the Interim Report or actions to be considered in the Final Report.

3.9.4.2 Public Workshops

Following the Regional Coordination Workshop, the Corps held 3 Public Workshops; April 10, 12, and 13, 2006. One workshop was held in each of the 3 coastal Mississippi counties, Jackson, Harrison, and Hancock. Invitations to participate in Public Workshops were made through a Mobile District Public Notice sent to standard environmental coordination mailing list, Mobile District press

releases sent to the media, and by Mobile staff contacts. We asked state, county and local officials to help get word of the workshops out to the public.

The purpose of the workshops was to review the ideas already gathered from previous involvement activities and gather additional ideas for inclusion in the MsCIP reports and plans. The workshops

were interactive and non-confrontational. Public participants were polled on project direction and the important principles of recovery that should be used in the plans. The public was invited to review the ideas already submitted and to add additional ideas or creative combinations of existing ideas to the list. Input could be provided via a network of PCs and structured questions. Alternative input opportunities for those uncomfortable or unable to respond via PC were also provided. Comment cards, post-it notes for maps, and a court reporter were available to capture ideas. From the Public Workshops, the list of MsCIP ideas grew to over 180. Again the MsCIP Team reviewed these ideas or potential projects for consideration as near-term projects in the Interim Report or actions to be considered in the Final Comprehensive Report. It should be noted that the residents of coastal Mississippi have been through a terrific ordeal. In some cases, their lives have returned to normal while in others the recovery process is just beginning. These conditions made acquiring public input difficult. Frequent comments were made that people were generally "tired of the storm and tired of meetings about the storm." In spite of that, needs and opportunities for specific areas were gathered from the public.

3.9.4.3 Website and Webcast

As discussed previously, the website (www.MSCIP.usace.army.mil) was established and maintained as a repository of MsCIP information and a different vehicle to allow interested public and agencies to provide comments and ideas including those who were displaced from there homes or could not attend the workshop opportunities. A webcast was created and provided on April 18, 2006 to allow those that could not attend the public workshops and online alternative for participating in the project. The webcast had conference call participation for all callers, a video and PowerPoint presentation delivered through a special webcast, polling, and a question and answer portion with Mobile District staff fielding questions.

3.9.5 Coordination with LaCPR

The MsCIP team took a systematic and regional integration approach with the Louisiana Coastal Protection and Restoration (LaCPR) study team. For a detailed account of this approach, please see the Main Report.

3.9.6 Public Input and Review of Planning Options: Round Two

3.9.6.1 Regional Coordination Workshop

The Round Two, Regional Coordination Workshop was held in Biloxi on April 26, 2006 with similar participants as Round One. The purpose of the Round Two Regional Coordination Workshop was to review the planning options that emerged from the Round One workshops. Prior to the workshop, participants were provided via the MsCIP website a list of ideas that emerged Round One and the screening criteria to be used to recommend near-term projects for inclusion in the Interim Report or retain them for evaluation in the Final Report. There was general understanding of the concept of near-term projects that can be implemented quickly to help in the immediate recovery of coastal Mississippi while the Comprehensive Plan is being developed. The screening criteria and their application to the potential projects were discussed. The Mobile District presented a preliminary, by-county, list of projects to be potentially recommended in the Interim Report. The potential near-term projects were discussed and none recommended for Interim Report received objection. However, participants requested review of a limited number of additional projects for inclusion in the Interim Report. As a result of this discussion, additional projects were considered and at least one additional potential near-term project (Jackson Marsh Restoration) was recommended for the Interim Report. No potential projects were deleted from consideration in the MSCIP, simply deferred to consideration in the Comprehensive Analysis and Final Report. Using these recommendations, the MsCIP team then began developing the structural lines of defense concepts. The MsCIP environmental and non-structural team analyzed environmental benefits anticipated from restoration while the other team assessed flood-proofing techniques.

3.9.6.2 Public Workshops

The Round Two, Public Workshops were held May 1, 2, and 4, 2006. The purpose of the Round Two Public Workshops was to review the planning options that emerged from the Round One workshops and discuss recommendations for near-term projects to be recommended in the Interim Report. The Mobile District presented a by-county list of projects to be potentially recommended in the Interim Report and the screening criteria for selecting those projects. None of the projects recommended for Interim Report received objection. However, participants requested and received clarification regarding why specific potential projects were not recommended as near-term projects. No potential projects were deleted from consideration in the MSCIP, simply deferred to consideration in the Comprehensive Analysis and Final Report. The MsCIP team had another public workshop on December 19, 2006 to present general ongoing efforts and to discuss conceptual solutions for coastal Mississippi. On April 5, 2007, the MsCIP team then presented detailed plans for environmental, non-structural, and structural plans to protect coastal Mississippi from future storms.

3.9.6.3 Web-site and Webcast

A Round Two webcast was created and provided on May 3, 18 to allow those that could not attend the public workshops and online alternative for participating in the project.

3.9.7 Public Scoping

Public and agency involvement has been a critical, early, and continuing part of the MsCIP project. Public and agency involvement accomplished to date has been a multi-step, and multi-component process. Persons and organizations having a potential interest in the proposed action, including minority, low-income, disadvantaged, and Native American groups, have been urged to participate in the environmental impact analysis process.

Scoping can lay a firm foundation for the rest of the decision-making process. Scoping is often the first contact between project planners and the public. The MsCIP team held many meetings prior to the actual formal Public Scoping meeting on 19 December 2006. These initial meetings were held due to the accelerated timeframe involved in preparing the 6-Month MsCIP Interim Report. At the December Public Scoping meeting, individuals presented their concerns to the MsCIP team and also to each other. The issues brought forth included concerns regarding construction of levees, preservation of the natural environment, impacts to natural resources especially wetlands regulatory permits for wetland fill, future growth, potential future storms, and etc. Possibilities and clarifications on initial thoughts were discussed during the Public Scoping meeting. This scoping process led the MsCIP team to think about the proposal early on, in order to explain it to the public and affected agencies. The participants were able to respond with their own concerns about significant issues. Incorporation of public and resource agency input will likely reduce the need for changes after the draft documentation is finished, because it reduces the chances of overlooking a significant issue or reasonable alternative.

4 PLANNING CONSTRAINTS

There are a number of issues that constrain the development of certain potential measures that might be used to address the identified problem set. Planning constraints are limited to laws and regulations that constrain the planning process. Among these include:

- Measures developed must not negatively impact the resources within the NPS's Gulf Islands National Seashore, particularly with respects from those constraints created by inclusion of Horn and Petit Bois Islands as Wilderness Areas;
- Measures developed must avoid, minimize, or mitigate any negative impacts to T&E species identified as residing within areas potentially impacted by study recommendations;
- Measures developed must be consistent with State of Mississippi Coastal Management Plan;
- Measures developed must meet the guidelines directed at maintenance of State Water Quality standards;
- Measures must be consistent with provisions of CWA;
- Measures must be consistent with provisions of NHPA;
- Measures must be consistent with Clean Air Act (CAA);
- Measures must be consistent with the ESA and the Fish and Wildlife Coordination Act (FWCA);
- Measures must be consistent with CBRA;
- Measures must be consistent with EO – Environmental Justice and Protection of Children; and
- Measures must be consistent with the Magnuson-Stevens Fishery Conservation and Management Act as amended by the Sustainable Fisheries Act of 1996.

5 INVENTORY AND FORECAST OF FUTURE CONDITIONS/RESOURCES

As mentioned earlier, six future "no-action" scenarios were developed to evaluate the impacts of plan components over time. The six scenarios were evaluated over a 100-year period of analysis

and include two redevelopment, and four sea-level rise scenarios. The first redevelopment scenario assumes the residential and commercial rebuilding that existed before Katrina will be built back as the same type (residential or commercial). The second rebuilding scenario assumes that a majority of the waterfront properties destroyed will be built back as commercial (i.e. high-rise condominiums). The three relative sea level rise scenarios are comprised of existing sea level, a moderate relative sea level rise, and high relative sea level rise. Scenario one is a residential redevelopment with no relative sea level rise over the 100-year period of analysis. Scenario two is a mixed residential and commercial redevelopment with no relative sea level rise, scenario three is a residential redevelopment with a maximum relative sea level rise depending on location of 2.0-feet over the period of analysis, scenario four is a mixed residential and commercial redevelopment and a maximum relative sea level rise of a 2.0-foot, scenario five is a residential redevelopment with a relative sea level rise depending on location of 3.4-feet, and scenario six is a mixed residential and commercial redevelopment with a maximum relative sea level rise depending on location of 3.4-feet. The detailed evaluation of these scenarios is outlined below, and a technical description of the calculation of relative sea level can be found in the Engineering Appendix.

The first round of inventory and forecast indicated that several future conditions scenarios should be revised. Key among these was the uncertainty of forecasts of future re-development and relative sea level rise. Future relative sea level rise is an especially important factor in defining conditions of the barrier islands, estuarine circulations, water quality, etc. A detailed discussion of relative sea level rise has been provided earlier in this report. As discussed earlier, this was accommodated by the inclusion of sensitivity analysis for both factors, to determine what effect alternative future scenarios might have on benefits, costs, and other considerations, under each scenario.

5.1 Forecasting of Future Re-development: Scenarios

The Mississippi Coast is rebuilding from the aftermath of the storms of 2005. Due to numerous factors (i.e. insurance payments, business opportunities, etc.), the exact rate at which re-development will continue to occur is not known. For this study an approximation was made based on the following assumptions:

- The structures destroyed as a result of Hurricane Katrina will be rebuilt and the population will return to at least pre-Katrina levels.
- Full redevelopment of structures will occur by 2012. Redevelopment is defined as the building back structures that existed before Hurricane Katrina, not development that occurs on land that was undeveloped.
- Redevelopment of the study area could take the form of residential redevelopment (exactly the way it was pre-Hurricane Katrina) or a mixture of commercial/condominium and residential redevelopment.
- FEMA guidelines require minimum heights that the first floor elevation must be built to in order to be included in the National Flood Insurance Program (NFIP). For the purposes of the redevelopment projected in this report, houses that will be rebuilt before the start of 2009 are assumed to be rebuilt to the Pre-Hurricane Katrina Base Flood Elevation (BFE) and those that are rebuilt between 2009 and 2011 will be rebuilt to the Advisory Base Flood Elevation (ABFE) as existed May 2007.
- The surge damage characteristics (by depth) of structures vary by the type of construction and are assumed to be similar to those in the New Orleans area (where this type of data is available). It is also assumed that the duration of surge inundation is approximately 24 hours, which is considered a short-term duration. The depth-to-damage relationships are explained in more detail in the Economic Appendix.

- A depreciated replacement cost of structures was used unless a structure was destroyed fifty percent or more due to surge from Hurricane Katrina. For those structures damaged fifty-percent or more and must be rebuilt, the full replacement cost was used to denote the value in the structure inventory.

Redevelopment is anticipated to occur as follows:

Table 18.

Redevelopment Assumptions

Assumptions of Structure Redevelopment by Year

Year	Percent Redeveloped	Height of Redevelopment
2005	N/A	Hurricane Katrina Landfall (August 29th)
2006	10%	Pre-Hurricane Katrina Base Flood Elevations
2007	25%	Pre-Hurricane Katrina Base Flood Elevations
2008	40%	Pre-Hurricane Katrina Base Flood Elevations
2009	60%	Advisory Base Flood Elevations
2010	80%	Advisory Base Flood Elevations
2011	100%	Advisory Base Flood Elevations
2012	Full Redevelopment	Base Year

5.2 Forecasting of Relative Sea Level Rise: Scenarios

In addition to redevelopment, relative sea level rise could also impact solutions (and decisions) to the water resource problems being evaluated along the Mississippi coast. The following scenarios were evaluated to account for relative sea level rise:

- Baseline. This is the current condition (or existing sea level) from where all other scenarios would be measured. This condition, although unlikely, must assume no further sea level rise (or land subsidence)
- Medium. This scenario assumes a relative sea level rise of about 2.4 feet over the 100-year period of analysis and is consistent with current Corps policy.
- Increased. This scenario assumes a relative sea level rise of about 3.4 feet over the 100-year period of analysis. This represents a reasonable upper bound of what could happen over the life of the project.

Because the scenarios are so wide-ranging geographically, and so dramatic in some reaches and not in others, one may need to examine the detailed results of the potential damage functions contained in the Economic Appendix to see what effect adding two feet, for instance, has on the number of structures that would be inundated in a given area, for a given event, and of a given frequency in 2012, versus those that would be inundated in Reach X for an event of a given frequency in 2111 (i.e., illustrating the differences over the 100-year planning horizon). There are few general statements, or statements that apply to the entire coast, that can be made for relative sea level rise. The single statement that applies is that sea level rise over the period of analysis, be it 50-year (used for evaluation of ecosystem restoration measures) or 100-year (used for storm damage reduction measures), would cause more damage over time, for an event of a given frequency. This is illustrated in Figure 9, below, which shows the increase in average annual damages for Hancock County, using 3 relative sea level rise scenarios.

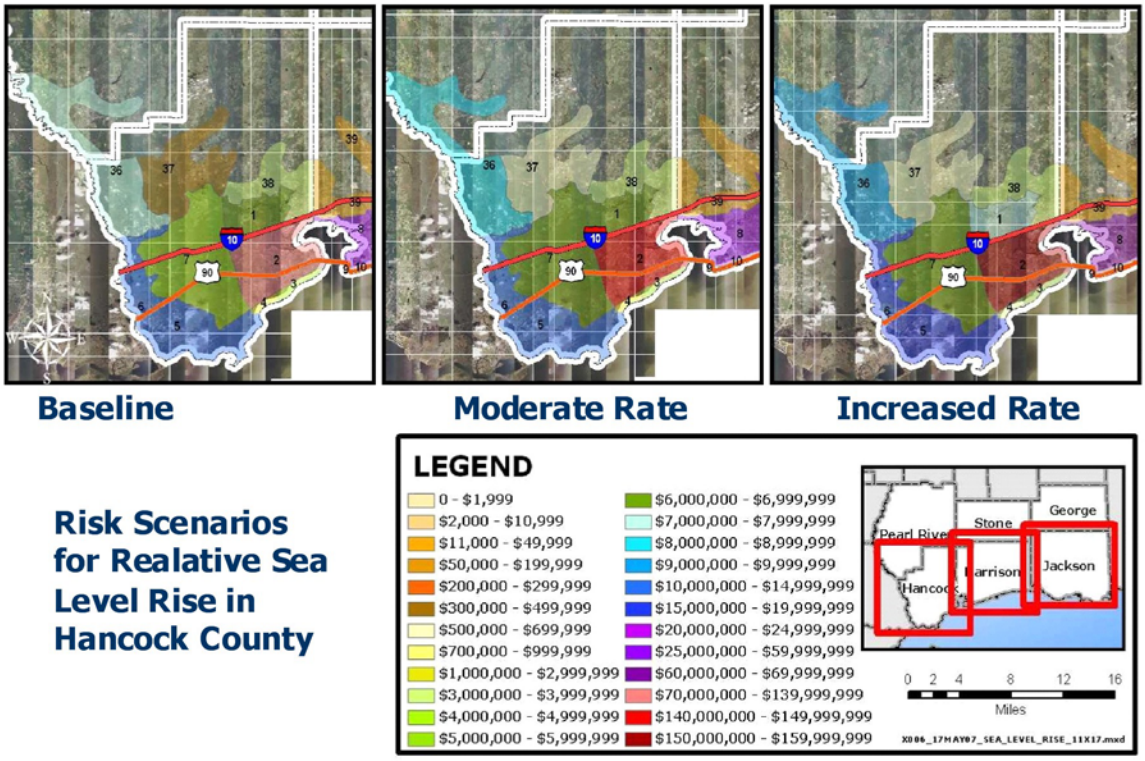

Figure 9 – Hancock County Annual Average Surge Damages by Sea Level Rise Scenario

It should be noted that the global debate over sea level rise is ongoing and the Corps will continue to design using the most up to date data available.

5.3 Preliminary Screening of Problem Areas

Following the initial identification of sites and problem areas, a preliminary screening analysis was conducted. Key to the success of this effort was the need to screen problem areas or sites that did not satisfy a link to:

- The problem being caused or exacerbated by the hurricanes of 2005;
- Based on the professional judgment of the study team that the problem area could not recover on its own;
- Congress' provided areas of investigation (storm damage reduction, erosion, fish and wildlife preservation [ecosystem restoration], saltwater intrusion, or related water resource issues;
- Ecosystem significance (scarcity of resource), from a national or regional perspective; and
- Being technically or environmentally feasible.
- Already being addressed by others.

The list of problem areas and sites screened as part of this process are shown in Table 19 below.

Table 19

Preliminary Screened List of Problem Areas

#	Name	Problem_Resolution/Status
1	Coastal Mississippi Hurricane Evacuation Plan	1. FEMA "Intergrated Public Alert and Warning System" update 2. State of MS. "Comperhensive Emergency Management Plan" update
2	Coastal Mississippi Artificial Reef Project for Remediation of 2005 Hurricane Damage	Mississippi Department of Marine Resources
5	USE selected levels of rip-rap instead of bulkheads for erosion control	Local Govermental Intities
7	Provide 100 acres of oyster reef restoration	MsCIP Interim & Comprehensive - Partnership with MDMR
8	Work with State to authorize transfer of development rights in state statutes	State of MS
9	Include repair standards in building codes	Local Govermental Intities
10	Dredge access channels to existing public marine industry and recreational boating	1. USCG clearing dredging tidal channels 2. FEMA evaluating remaining channels for debris and sediment removal
13	Form a monitroing network network that will survive and function throughout a major storm to provide data that is critical to emergency managers	FEMA "Intergrated Public Alert and Warning System" update
14	Provide an incentive for replacing failing septic systems in rural areas to improve water quality along bayous and bays.	1. Section 592 Program 2. State Regional Water and Wastewater Authority
17	Complete snagging/clearing, etc. to restore the capacity of existing drainage.	1. MsCIP, four Interim projects and recommendation for Forrest Heights 2. Jackson County Permitted for six drainage ways 3. FEMA evaluating remaining channels for debris and sediment removal
18	Repair existing bulkheads or other structural drainage components that were damaged during the storm to reduce future failures during similar events.	1. MsCIP, two Interim projects- Jackson Marsh, Courhouse Road 2. FCCE, Harrison County Beach project 3. City of Pascagoula has repaired
19	Maximize Beneficial Use of Dredge Materials	1. MsCIP Barrier Island recommendation 2. FCCE, Harrison County Beach project
20	Consider brown water system to minimize demand on ground and surface waters and limit saltwater intrusion.	USEPA
21	Re-establish Benchmark Information Coastal-wide	FEMA
22	Relocate wastewater treatment facilities out of the surge-prone areas	State Regional Water and Wastewater Authority
23	Inspect and Rehabilitate Wastewater and Piping Systems	State Regional Water and Wastewater Authority
28	Barrier Isalands - Remove hazardous materials	Other
30	Barrier Islands - Protect From Spills	Other
31	Barrier Islands - Evaluate Sediment Transport - Ensure sand minimg does not Impact Islands	1. MsCIP Barrier Island recommendation 2. MsCIP/ERDC Sediment Budget evaluation

#	Name	Problem_Resolution/Status
34	Partnership Efforts with Louisiana to Marsh Island Areas	LaCPR Comprehensive
37	Provide protection for public facility (i.e., WW treatment plants).	1. State of MS Regional Water & Wastewater Authority via FDA funds. 2. MsCIP LOD-4 recommendation
38	Bay St. Louis Downtown HSDR	MsCIP Interim Project
39	Cowand Point Seawall Erosion Control	MsCIP Interim Project
40	Hancock County Beach Ecosystem Restoration and HSDR	MsCIP Interim Project
41	Clermont Harbor Seawall HSDR and Erosion Control	MsCIP Interim Project
42	Hancock County Comprehensive HSD - Ecosystem Restoration	MsCIP Interim & Comprehensive Echosystem Restoration Recommendation
43	Jackson Wetland Restoration	MsCIP Interim Project
44	Bayou Caddy Shore Protection and Ecosystem Restoration	MsCIP Interim Project
46	Lakeshore Beach Ecosystem Restoration	State of MS - Environmental Concerns - Potential SAVs
48	Hancock County Communities Flood Damage Reduction	MsCIP Interim Project
49	WhiteÆs Road Evacuation Route Protection	State of MS. "Comperhensive Emergency Management Plan" update
55	Restore more natural freshwater flows by closing the MRGO	USACE-MVN is funded to close MRGO
56	Remove storm debris (i.e., demolition debris carried in by surge retreat) from aquatic environments. Restore traditional shrimping and fishing areas rendered un-trawlable by storm debris.	1. City of Pascagoula funded to construct Boardwalk 2. MsCIP to construct Beach along entire sound-front from city park westward 3. MsCIP Environmental Restoration recommendation
57	Ferries to Temporarily Replace Bridges.	State of Mississippi, Bridges Repaied
59	Restore Hancock County Beaches to Pre-Katrina conditions	1. MsCIP Interim Project Dunes Only
60	Widen Hancock County Beaches, jump-start dunes	1. MsCIP Interim Project Dunes Only
61	Preserve Bayou Caddy Area	MsCIP Interim Project
62	Protect Hancock County wetlands from filling for development	1. MsCIP Envronmental restoration recommendation 2. MsCIP Regulatory Collaboration
63	Construct a N/S rail link connecting Port Beinville Industrial Park to the Norfolk and Southern Railroad through Stennis Buffer. Hurricanes cause CSXT rail outages which cost > $20,000/day	State of Mississippi and Congressional Representatives
64	Open the east Pearl River channel so it can be used by commercial marine traffic from Port Bienville	USCG

#	Name	Problem_Resolution/Status
66	Mississippi Coastal Pump Station Inundation Protection	1. State of MS Regional Water & Wastewater Authority via FDA funds. 2. MsCIP LOD-4 recommendation
68	Mississippi Coastal Barrier Island Restoration	MsCIP & NPS Barrier Island restoration recommendation
69	Mississippi Coastal Improvement and Hurricane Storm Damage Reduction Program	Mississippi Department of Marine Resources
70	WhiteÆs Road Evacuation Route Protection	FEMA evaluating remaining channels for debris and sediment removal
71	WhiteÆs Road Evacuation Route Protection	FEMA evaluating remaining channels for debris and sediment removal
72	Harrison County Beach Ecosystem Restoration and Erosion Control	MsCIP Interim Project
73	Long Beach Harbor HSDR	Harrison County Beach Authority
74	Highway 90 û Rodeburg to St. Charles St. HSDR and Flood Control	State of Mississippi DOT
75	Pass Christian Harbor HSDR	Harrison County Beach Authority
78	Gulfport Commercial Harbor	State of Mississippi Port Authority
80	Turkey Creek Flood Damage Reduction	1. MsCIP Forrest Heights Levee Recommendation 2. MsCIP Regulatory Collaboration 3. MsCIP Interim Project at Long Beach
81	North Gulfport Interior Drainage	1. FEMA evaluating remaining channels for debris and sediment removal 2. MsCIP Interim Project at Long Beach
82	Long Beach Interior Drainage HSDR (includes Canals 2 - 3)	MsCIP Interim Project
83	Harrison County Industrial Seaway Harbor of Refuge	State of Mississippi
85	Courthouse Road Wetlands Ecosystem Restoration and Preservation	MsCIP Interim Project
91	Extend South Side of Deer Island. Extend 200 yards to repair breach in island and restore original footprint of island.	SAM FCCE Project
92	Deer Island enhancements. Cap shell middens on western side of the island and restore top soil in maritime live oak forest	Section 528 Construction General & FCCE Funds
93	New Sewage Treatment Plant in Woolmarket Lagoon Area - Move the Woolmarket Lagoon to north of I10 north of the area. would protect the citizens by moving the sewage from the flood prone areas:	State Regional Water and Wastewater Authority
94	Flood-Proof Existing Infrastructure	State Regional Water and Wastewater Authority
95	Enhance Lee and Bayview Docks for commercial shrimpers.	Other Local and State Entities
96	Enhance Maine Street Docks for commercial shrimpers.	Other Local and State Entities
98	Develop Concrete Staging Center in Industrial Canal. Develop Harrison county industrial canal artificial reef staging area to stockpile concrete debris for oyster reef and other useful projects.	MDMR and MsCIP Comprehensive - Partnership with State

#	Name	Problem_Resolution/Status
99	Restore or enhance Mississippi oyster reefs.	Mississippi Department of Marine Resources
100	Open hw 90 Bridges quickly	State of Mississippi DOT - Bridges are Open
101	Utilize HW 90 bridge as artificial reef material	State of Mississippi DOT
103	Economic Development of Downtowns. Orderly expansion of municipal harbors along with revitalization of downtowns would provide green space; non-water dependent retail, and a manageable beach blvd. (NOT HW 90).	State of Mississippi, Governors Renewal Initiative State of Mississippi Port Authority State of Mississippi DOT Alternate Hwy 90 proposal
105	Complete the purchase of “optional” Cat Island for inclusion into Gulf Islands Nationals Seashore	National Park Service
106	Rebuild the Harrison County boardwalk with concrete to accommodate pedestrians, BICYCLES, and possibly street vendors.	Harrison County Beach Authority
107	Provide inland marine vessel storm shelter location with adequate moorings.	State and Local Entities
113	Reconsider dioxin cleanup on navy base post Katrina.	USEPA
114	Long Beach Interior Drainage HSDR (includes ôCanals 2 - 3)	MsCIP Interim Project
115	Reduce toxic exposure which exacerbates storm damage – Dioxin, Creosote, Titanium Dioxide, Gypsum.	FEMA evaluating area regarding hazardous materials
116	Turkey Creek watershed Greenway	MsCIP Comprehensive Future Studies and Gulf Coast Trails
117	Forrest Height Levee :- Restore; Vegetate with native species; Footbridges; Nature trail atop	1. MsCIP Forrest Heights Levee Recommendation 2. Rivers, Trails and Conservation Assistance Program
118	Dredge shoaled channels hinfering storm evacuation	FEMA evaluating remaining channels for debris and sediment removal
119	Dredge shoaled marinas	US Coast Guard
120	Deer Island re-nourishment of south side.	SAM Project Section 528
122	Possibly add height to the existing beach elevation and redevelop lost dune vegetation.	1. MsCIP Interim Project 2. SAM FCCE Harrison County Beach Restoration Project 3. MsCIP Comprehensive, LOD 2
123	Flood-proof low-lying sewer treatment plants. Lift stations and wells and their electrical and electronic controls.	State of Mississippi Regional Water and Wastewater Authority
128	Shearwater Bridge Erosion Control	MsCIP Interim Project
131	Pascagoula Beach Blvd. Restoration	MsCIP Interim Project
133	Beach Boulevard Erosion Control	MsCIP interim Beach Project
135	Chicot Road Flood Damage Reduction	City of Pascagoula
138	Upper Bayou Cassotte Flood Damage Reduction	MsCIP Interim Project
142	Greenwood Island Ecosystem Restoration	State of Mississippi
146	Old Spanish Trail Comprehensive Flood Damage Reduction/Drainage	1. MsCIP Comprehensive - Non-Structural/SDSS for further evaluation

#	Name	Problem_Resolution/Status
		2. FEMA evaluating remaining channels for debris and sediment removal
147	Old Spanish Trail Comprehensive Flood Damage Reduction	FEMA evaluating remaining channels for debris and sediment removal
148	Old Spanish Trail Comprehensive Flood Damage Reduction	1. MsCIP Interim Project 2. NRCS Recovery Project
150	Franklin Creek Floodplain Restoration/Franklin Creek and Pecan Hydrology Project	MsCIP Interim Project
152	Gautier Hurricane Storm Damage Reduction and Ecosystem Restoration/Ladnir Rd	1. MsCIP Interim Project 2. Coast Guard Dredging Project 3. FEMA evaluating remaining channels for debris and sediment removal
153	Bayou Chico Beach HSDR/Bayou Chico Bulkhead Rehabilitation	Local Governmental Entities
154	Round Island Ecosystem Restoration/Round Island Lighthouse Relocation	State of MS
155	Upper Old Fort Bayou Comprehensive Flood Damage Reduction/ C. Byrd Road Drainage	1. MsCIP Comprehensive - Non-Structural/SDSS for further evaluation 2. FEMA evaluating remaining channels for debris and sediment removal
156	Upper Old Fort Bayou Comprehensive Flood Damage Reduction/ C. Byrd Road Drainage	1. MsCIP Comprehensive - Nonstructural/SDSS 2. FEMA evaluating remaining channels for debris and sediment removal
157	Pascagoula beaches, offshore breakwater/dunes/reefs/marshes to dissipate wave energy	MsCIP Intreim Project
158	Restore natural drainage ways upper Bayou Castelle (vic Fishhawk Rd, Meadow Dale Dr., Longwod Dr, and Bayou Castelle Dr)	1. MsCIP Comprehensive - Nonstructural/SDSS 2. FEMA evaluating remaining channels for debris and sediment removal
159	Restore natural drainage ways upper Sioux Bayou (vic Laville Subdivision and Westgate Subdivision)	FEMA evaluating remaining channels for debris and sediment removal
160	Restore natural drainage ways upper Mary Walker Bayou (vic Northwood Hills, Rolling Meadows, and Bayou Oaks subdivisions)	FEMA evaluating remaining channels for debris and sediment removal
165	Pascagoula Beach Restoration. Dunes, grasses, trees, with intermittent pockets of sand beach	MsCIP Interim Project
166	W Land Lake Pascagoula. Dredge to recover retention qualities and install new drainage pipes to north.	FEMA evaluating remaining channels for debris and sediment removal
168	Study same as 58	FEMA evaluating remaining channels for debris and sediment removal
169	11th St Bridge and Drainage Canal. Bridge is failing and canal walls are caving in.	Jackson County Road Repair
170	Drainage improvements - same as 65	FEMA evaluating remaining channels for debris and sediment removal
171	Old Mobile Hwy Bridge Failing	Jackson County Road Repair

#	Name	Problem_Resolution/Status
172	Bridge at Old Mobile Highway and Hospital Road is Damaged	Jackson County Road Repair
173	Restore Bates St Drainage to Open Water	FEMA evaluating remaining channels for debris and sediment removal
174	Inspection & Rehabilitation of Sewer and Storm Piping for Pascagoula	MVK Section 592 Program
175	Relocate Pascagoula WWTP out of surge area	State of Mississippi Regional Water and Wastewater Authority
176	Re-establish benchmarks Pascagoula city-wide	FEMA
177	Pascagoula brown water system study	State of Mississippi Regional Water and Wastewater Authority
178	Pascagoula Beach Blvd. Restoration (Boardwalk, beach, and marsh addition along Pascagoula front beach)	1. MsCIP Interim Project 2. City of Pascagoula Renewal Project
179	11th St Bulkhead Rehab	City of Pascagoula
180	Pascagoula main drainage system restoration including additional wetland side storage. City-wide retention/detention system. Drain barrier valve system.	1. MVK Section 592 Program 2. State of Mississippi Regional Water and Wastewater Authority 3. MsCIP Comprehensive - Nonstructural/SDSS for wetland Evaluation
181	C. Byrd Road Drainage	1. MsCIP Comprehensive - Non-Structural/SDSS for further evaluation 2. FEMA evaluating remaining channels for debris and sediment removal
183	Use jetties to prevent sediment flow clogging channels	Local Governmental Entities
186	Dredge/clear area in front of beachfront outfalls.	1.MsCIP Interim at Pascagoula 2. MsCIP Comprehensive, LOD 2 at Ocean Springs
188	Improve the Jackson-county seawall. Provide additional county-wide seawall construction, boardwalks, beach construction, marsh construction, or a combination of these elements	1. Mississippi Rebuild Renew Initiative 2. MsCIP Interim Projects
189	Gautier improvements to drainage. Same as 158.	1. MsCIP Comprehensive - Nonstructural/SDSS 2. FEMA evaluating remaining channels for debris and sediment removal
190	Gautier, drainage improvements. Same as 159	1. MsCIP Comprehensive - Nonstructural/SDSS 2. FEMA evaluating remaining channels for debris and sediment removal
191	Bayou Outlets on the Mississippi Sound that require actions to remove deposited siltation	1. MsCIP Interim Project 2. Coast Guard Dredging Project 3. FEMA evaluating remaining channels for debris and sediment removal
192	Gautier improvements to drainage. Same as D.	FEMA evaluating remaining channels for debris and sediment removal
193	Dredge Davis & Simmons Bayous to include all connecting bayous to help prevent flooding.	FEMA evaluating remaining channels for debris and sediment removal
194	Rebuild and enlarge Marsh Island	State of Mississippi

1

6 FORMULATION ROUND ONE

After narrowing the list of problem areas, the MsCIP study team developed potential problem-solving measures. The initial measures were developed independently within the structural, environmental, and nonstructural sub-teams and then later evaluated by the entire group. These potential measures were also solicited at each of the Regional Coordination, agency, and public workshops, and through detailed discussion with the entire study team. In order to not short-cut the planning process, and to ensure that good ideas were allowed to proceed through the process, a simple definition of a potential *measure* was provided to the team members, as "a feature or activity at a particular site". This definition was reiterated over and over to the formulators of measures, as the team progressed through this phase and following phases of formulation.

Formulation of measures to reduce storm damage, reduce coastal erosion, restore damaged ecosystems, or deal with saltwater intrusion, generally fell under the category of *Engineering solutions* in the case of the first two issues, or under the category of *Environmental solutions*, in the case of the last two issues.

6.1 Development of the No Action Plan

NEPA regulations (40 CFR 1502.14(d)) require that no action always be considered a viable alternative in any final array of plans. The no-action plan is the default choice. The planning process is built on the default assumption that the Corps should do nothing to address the problems and opportunities. The Corps should become involved in a project only if it is better for society than doing nothing. Hence, the planning process must convincingly demonstrate that involvement in some project is preferred over no action by the agency. In other words, one should not overlook the importance of the first decision to be made at this step, should something be done? The "no action" alternative is the same as the 'without project' condition described in more detail in the Main Report.

The most notable adverse changes that would occur as a result of no actions being taken are within the areas of flood damages and fish and wildlife. It is anticipated there would be little or no change within the existing soils, sediments, climate, air quality, water supply, and geology of coastal Mississippi. Due to the current rebuilding throughout the coast, slight increases in noise could occur during rebuilding construction activities. It is anticipated that these disturbances would be temporary and have only minor impacts to the community.

The wetland community will likely suffer the most significant impacts under the no action alternative. A large amount of exotic specie vegetation has been colonizing parts of coastal Mississippi following the storms of 2005. Hurricane Katrina left extensive debris fields and sedimentation in the area destroying many native trees and vegetation. Due to the loss of the native species, this area has experienced a severe infestation of the invasive Chinese Tallow tree, which is invading the marshes and adjacent flatwoods. The native species of wetland vegetation act as filters removing pollution from runoff, and allow these areas to act as natural buffers improving water quality, storing floodwaters, and reducing erosion. Exotic species, however, outcompete the native vegetation so that it negatively alters the hydrology of the wetlands, reduces the available food source for fish and wildlife, and degrades the entire wetland community by impeding the natural biogeochemical process. Exotic vegetation would continue to persist under the no action alternative, and eventually worsen.

It is anticipated there would be a slight recovery of the vegetation within various habitats such as dune plants, emergent marshes, and pine savannah wetlands under the no action alternative, but these areas would also generally degrade over time. Further fragmentation of once contiguous

wildlife corridors in the northern reaches of the study area will also continue to occur as new development continues to move further away from the coast.

Tidal habitat for fish and wildlife (i.e. barrier islands, marsh habitat, wet pine savannah, etc.) may also be adversely impacted under the no action alternative. Many marine species depend on sea grass beds that were destroyed during Hurricane Katrina for foraging opportunities and cover. An increase in saltwater intrusion will continue to degrade the estuarine environment of the Mississippi Sound. Examples of the species that are dependent on this type of habitat are oysters, shrimp, crabs, finfish, coastal shore birds, and sea birds.

Many threatened and endangered species (i.e. Sandhill Crane, piping plover, etc.) could also be adversely impacted under the no action plan. Their continuing loss of habitat could occur as development and further degradation occurs.

With no Federal action, the city's municipal services would not likely be relocated and the badly damaged or uninhabitable structures would have to be reconstructed in the same area as funding becomes available. It would also likely result in changes to existing land uses. The city of Biloxi in Harrison County is experiencing record number building permit requests for waterfront development, such as condominiums and commercial businesses. In fact, the number of building permit requests has increased to about six times more than prior to Hurricane Katrina. While over time the building rate should level off, building is still likely to continue under the no action plan, even into areas that are not suitable to support development.

Significant impacts to the cultural resources would likely occur under the no action alternative. Archaeological and architectural studies along the Mississippi Gulf Coast have documented the destruction caused by natural forces, most notably hurricanes. Standing structures are often the most dramatic and visible witnesses to this destruction. However, prehistoric and historic archaeological sites are also extremely vulnerable. Shell middens, found along the immediate shoreline and within coastal marshes and estuaries, often are flipped and re-deposited by the storm surge and wave action of hurricanes. This effectively destroys much of the value of the sites. Historic Indian villages and historic town sites, such as those along the bluff on Bay St. Louis, could be destroyed by continued exposure to wave action. In addition, post storm activities offer many more mechanisms for site destruction. These include clearing of timber by use of skidders and other heavy equipment, debris removal, and reconstruction. The destructiveness of these activities is well documented from the years following hurricane Camille which struck the area in 1969. Hurricane Katrina has been documented to have destroyed a vast majority of the standing historic properties within Hancock County, and a large number of those within Harrison and Jackson Counties. Future storms will likely continue this trend under the no action alternative. For a more detailed discussion on storm surge damages, please see the Economic Appendix.

6.2 Development of Storm Damage Reduction and Erosion Reduction Measures

Examples of preliminary measures for storm damage reduction, supplied by the study team, agencies, and public, included:

- Levees, seawalls, or embankments (barriers to surge);
- Gates, berms, and breakwaters (barriers to surge);
- Elevating structures (elevation above inundated area);
- Acquisition and removal from high-risk areas (removal from high-risk inundation zones);

- Zoning and Building Code modification (removal of the most damageable or critical infrastructure or services from highest risk areas);
- Floodplain Management (removal of the most damageable or critical infrastructure or services from highest risk areas);
- Moving back from the shoreline (removal of the most at-risk development, most damageable or critical infrastructure, or services from highest risk areas);

Examples of preliminary measures for erosion reduction, supplied by the study team and public, included:

- Placement of additional sand;
- Placement of harder erosion-control features, such as shell materials, construction debris, rubble, stone, geo-textiles;
- Supply of additional sand to littoral zone;
- Reduction of sand-robbing activities in the near-shore or barrier island zones.

Additional measures were added later, as more factual information became available, and as more input was provided and more technical results became available.

6.3 Development of Ecosystem Restoration, Preservation of Fish and Wildlife and Saltwater Intrusion Reduction Measures

Examples of preliminary measures for ecosystem restoration and fish and wildlife preservation, supplied by the study team and public, included:

- Removal of sediment and/or debris, choking streams and estuaries;
- Re-grading to historic conditions and topography;
- Removal of invasive species;
- Removal of dead vegetation, deadfalls, and other vegetation that interferes with natural functions;
- Planting of native species in areas in which those species were killed by the hurricanes; and
- Filling of drainage channels that interfere with natural functions.

Examples of preliminary measures for saltwater intrusion (actually encroachment into a freshwater body) reduction, supplied by the study team and public, included:

- Reallocation of freshwater supply by re-regulation of reservoirs and
- Diversion of freshwater sources to direct more freshwater into areas of critical need.

The list of potential measures that applies to each site was crafted to that specific site based on its characteristics. More detail is provided on the list of potential measures within its appropriate appendix.

Formulation of these preliminary measures was also based on consideration of both what resources it would reduce damages to (i.e. - targeted developed areas of the coast or targeted ecosystem

features), as well as the potential negative outcomes it might cause (i.e. - induced flooding). All of the structural measures were also formulated in such a way that they could be laid out as either stand-alone concepts, or as components of a multi-featured plan for a given area (i.e. – structural, nonstructural, or ecosystem restoration plan).

6.4 Evaluation of Measures: General Discussion

Each problem area or site was then evaluated to determine the level of effort required for more detailed development of solutions, the need for more rigorous technical analyses (such as detailed modeling), the need for more detailed environmental analysis related to its implementation and long-term effects, such as the potential for impacts to sensitive, threatened or endangered species or habitats, and a host of other factors. Evaluation at this phase of study was based on discussion between study team members and technical experts, on the results of preliminary modeling of potential storm surge, for instance, or, in the case of ecosystem restoration, calculation of potential improvement output, to determine the relative potential damage reduction or environmental output improvement achievable, and problems encountered or solved.

6.5 Evaluation of Storm Damage Reduction and Erosion Reduction Measures

Early evaluation indicated many areas of the coast that are not highly developed, and other areas that contain significant obstacles to formulation of structural measures. Many areas were found to be extremely difficult to reduce damages when using structural measures, compared to areas such as those in certain areas of Harrison County, where the entire coastline is densely developed, but have lesser degrees of environmental resource concentration. Many outlying areas were found to require individual means to achieve storm damage reduction.

Almost any problem area or site along the Mississippi coastline was found to have environmental considerations that required adjustment or modification of formulated structural measures to address those concerns. However, in Jackson County, the Pascagoula River system separates the city of Pascagoula from most of the coast to the west. This river system with its vast marshes areas is one of the last major free-flowing rivers in the southeast, and has numerous environmental resource concerns. In the western portion of the state, extensive mashes create other concerns along with the Pearl River that separates Mississippi from Louisiana. Other technical issues also made structural damage reduction in these areas problematic.

Review of the coastline in Mississippi using aerial photographs, topographic maps, LIDAR surveys, and storm inundation data revealed that natural topography could play a major role in forming storm barriers. Other features such as the offshore barrier islands, extensive beaches in many areas, and existing beach-front roadways were also determined to have a substantial role in potential damage reduction. The modeling also indicated that the high ground followed by the CSX Railway crossing the entire state near the coast, functioned as a barrier to surge during Katrina, and thus, should be considered as a potential inland barrier during future events.

Review of the inundation maps generated during the surge modeling of Katrina and other events also indicated that the extensive low-lying areas associated with two bays that extend inland from the coast would require more refined methods than a simple barrier, to solve the surge inundation issue. It was apparent that any continuous storm protection systems would have to consider these as breaks in the line. Closing off rivers and bays with surge gates have been used in Europe to protect inland areas and different designs of gate structure had to be evaluated and considered in the development of comprehensive plans for coastal Mississippi.

6.6 Evaluation of Ecosystem Restoration and Saltwater Intrusion Reduction Measures

The following four models were utilized by the MsCIP environmental PDT to evaluate the performance of potential ecosystem restoration measures:

- Mississippi and Alabama Gulf Coast Tidal Fringe HGM;
- Wet Pine Savannah HGM;
- FHI Model for Evaluation of Coastal Maritime Forest/Beach-Dune Habitat; and
- GIS-tool Wetland Restoration SDSS Model.

The HGM and FHI models are discussed in more detail in the Environmental Appendix.

In addition to HGM and FHI, a SDSS model, which related areas of hydric soils and other factors related to long-term survivability of a wetlands resource, was also used as a formulation, evaluation, and ultimately, screening tool. The SDSS model scales and combines multiple GIS layers for the purpose of identifying and evaluating potential wetland restoration sites within the three coastal counties. The results of the model were used in conjunction with local expertise to evaluate potential wetland restoration areas.

The results of the HGM modeling were used for functional assessment of existing and future "without-project", and also preliminary "with-project" measure assessment, of both tidal fringe wetlands and wet pine savannahs habitats. The tidal fringe HGM model was also used to evaluate impacts to tidal fringe wetlands that would result from levee alignments including various ring levee alignments. The functional assessments helped to determine mitigation requirements for unavoidable wetland impacts by structural components of the comprehensive plan. The wet pine savannah HGM allowed the team to assess impacts to wet pine savannah habitats at several of the recommended environmental sites.

The results of the FHI modeling was used for functional assessment of existing and future "without-project", and also preliminary "with-project" measure assessment, of all potential coastal maritime forests/beach-dune habitat restoration measures.

Future with-project condition scores, established by the study team's modeling analysis of the specific functions that would be modified, either positively or negatively, at each site, plus "No-Action", existing and future "without-project" score, are shown in the Environmental Appendix, by site or problem area.

Evaluation of saltwater intrusion reduction methods involved the investigation of freshwater diversion measures at several locations. These would divert freshwater from the Mississippi River or other sources as a mechanism to promote a reverse of the recent increases in salinity in the Mississippi Sound/Biloxi marshes areas. This would support fresher marshes and oyster reef health and productivity, thus enhancing both their economic value and the ecological services they provide.

In an effort to initiate the proper evaluation of freshwater diversions, a water quality model (WQM), which is based on the CE-QUAL-ICM water quality model code, is coupled to output from a three-dimensional hydrodynamic model of the region, which is based on the CH3D hydrodynamic model. The version of CH3D with sigma coordinate in the vertical dimension is being used. The model grid extends seaward beyond the Chandeleur Islands and includes Mobile Bay, Lake Borgne, Lake Pontchartrain, the Inner Harbor Navigation Channel of New Orleans and the Mississippi River Gulf Outlet Channel. Predicted water quality constituents, including nutrients, phytoplankton, dissolved

oxygen, temperature, salinity, and underwater light intensity were evaluated for several scenarios and compared to modeled existing baseline conditions to assess relative changes.

The WQM was applied at three locations: (1) a diversion of freshwater flow from the Mississippi River at Bonnet Carre' spillway, (2) a diversion of freshwater flow from the Mississippi River at Violet Marsh, and (3) a diversion of all of the Escatawpa River flow into Grand Bay. The modeled release of water at the Bonnet Carre' diversion was varied by month, and the Violet Marsh model was designed to have a constant flow. The Escatawpa diversion was modeled after the flow that occurred in the Escatawpa River during 1998. The WQM was applied for the period April through September 1998. The hydrology model was run with the same conditions as used for the base conditions used in the WQM calibrations for 1998 except that the additional freshwater flows were introduced.

6.7 Comparing Measures: Formulation Round One

Each preliminary measure (potential solution, activity, or feature) for each problem area or site was then compared to other measures developed for that site or problem area. Again, comparison at this phase of study was based on discussion between study team members and technical experts, to determine the *relative* potential damage reduction or environmental output achievable, and problems encountered or solved, particularly in comparison with the "No-Action" Plan, or the condition in which no action is taken to solve as problem or provide the means for improvement of a given degraded condition or set of circumstances.

Comparison of structural and non-structural damage reduction measures, and erosion control measures, was done by comparison of their relative ability to reduce damages, with consideration given as to their potential environmental mitigation requirements or negative impacts, potential costs, and other potential issues. Comparison of ecosystem restoration measures, and saltwater intrusion measures, by the means discussed in the immediately preceding sections, was done by comparison of their relative ability to achieve the previously-discussed criteria, as well as their potential costs, and potential environmental outputs as compared to the "No-Action" Plan.

6.8 Screening Measures: Formulation Round One

6.8.1 Initial Screening Criteria

After the preliminary screening of problem areas and sites, and development and evaluation of measures was developed for each problem area, the list of problem areas and sites was then screened based on the input of the inter-disciplinary study team's understanding of each site's potential to meet a variety of criteria.

For storm damage reduction or erosion reduction, the site or problem area had to have:

- **Technical feasibility** (i.e., will a given measure provide a sound technical solution to the identified problem(s)?), and thus, at least one technically-feasible solution from the above list;
- **Environmental feasibility** (i.e., will a given measure provide a sound solution to the identified problem(s), without creating environmental resource problem of its own?), and;
- There were identified some potentially **cost-effective** solutions to the identified problem suite.

For ecosystem restoration or saltwater intrusion reduction, the site or problem area had to be identified as having:

- no ability to either heal on its own, unaided by human intervention, or;
- national and/or regional significance in regards to the type of ecosystem it represents;
- the need for assistance to restore vital hydrologic links;
- the potential need to manually remove blockages created by hurricane-deposited debris that was impacting function;
- the potential need to remove excess sediment deposited by the hurricanes that had changed the nature of the land's surface and resulted in degraded function and value;
- the potential need to remove invasive species that had entered the area since the hurricanes and caused displacement of native plant species (and potentially wildlife depending on native species), degrading function of the ecosystem;
- or the potential need for planting of native species vital to restoration of a significant ecosystem and restoration of its functions and values.

6.8.2 Screening of Preliminary Measures

The MsCIP planning process required this screening process to "weed out" unproductive measures, or those that did not meet the planning objectives. Application of the screening criteria above resulted in the screening of a large number of less significant areas, as well as many that the study team determined were capable of recovery on their own.

Additionally, as more technical and environmental data became available, more judgment is able to be applied as to the relative value of any given measure, when compared to others applied to that same site or problem area. Preliminary analysis again indicated that there were many solutions or measures that were *obviously* cost-prohibitive, unequivocally environmentally damaging, or simply technically infeasible, when compared to other measures, when each problem area or site was evaluated individually.

Due to the large number of measures involved, and the fact that initial evaluation and screening was done on a case-by-case basis by the study team in the field or in discussion held for each site, no detailed discussion of each of them is contained here, although numerous preliminary measures and their evaluation, comparison, and screening are referenced in the Engineering and Environmental appendices.

The screened list of remaining ecosystem problem areas and sites was narrowed to the following:

- Restoration of barrier islands. Includes entire restoration of the MS barrier islands including littoral placement, re-vegetation, and restoration of Submerged Aquatic Vegetation.
- Restoration of Dune habitat. Using dune barriers along the MS coast as either an ecosystem restoration measure, or in combination with dune use as a storm damage reduction barrier.
- Reduction of saltwater intrusion by restoring fresh water flows from the Escatawpa, Pearl, and Mississippi Rivers.
- Restoration of coastal Mississippi wetlands and forests by evaluating historical wetland areas, frequently flooded populated areas, and current wetland and forest areas degraded by the storms of 2005.

For damage reduction concepts, a structural "Lines of Defense" concept (see Figure 11) was developed that started with the offshore barrier islands and progressed inland to what could be considered the surge extent of the worst possible theoretical storm. This storm, labeled the

Maximum Possible Intensity (MPI) event would be used to define a line, based on ground surface elevation that the storm surge would not exceed. The lines of defense would be designed to provide increasing levels of protection as you transgressed inland. Some lines would not provide protection from large storms, and several areas of the coast could not be included in continuous line of defense. These areas would be either placed in a ring levee system or designated to a non-structural solution during the second round of evaluation.

Many types of structural and nonstructural protection were reviewed. Some examples of the types of measures that were screened out due to a lack of technical feasibility are identified below and depicted in Figure 10.

- Inflatable barriers,
- Concrete sidewalks or roadways that could be hydraulically rotated upwards to form a seawall,
- Sliding panel gates, and
- Offshore breakwaters.
- Contiguous Barrier Island 'Wall'
- Galveston type Seawall

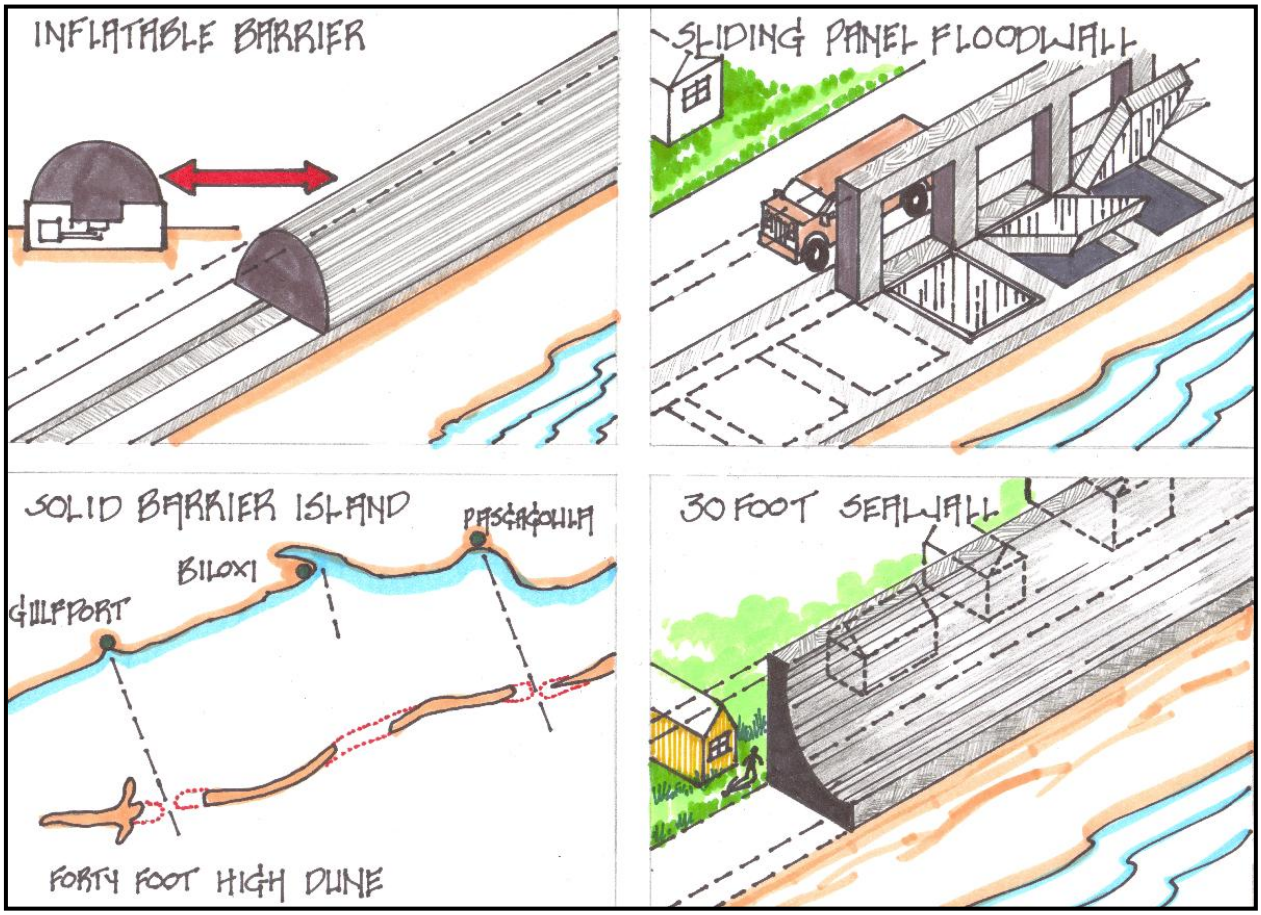

Figure 10 Preliminary Damage Reduction Measures Screened Out

The screened list of damage reduction concepts and/or alignments includes the following for further analyses and depicted in Figure 11:

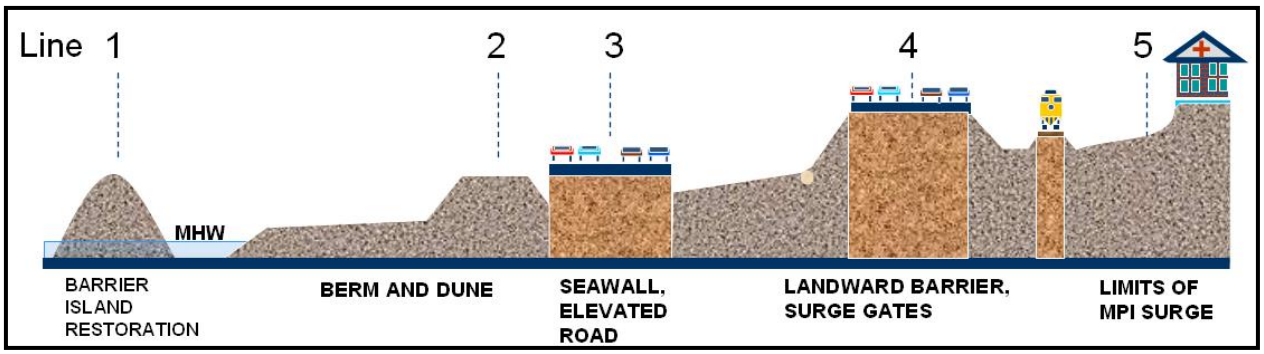

Figure 11 Lines of Defense Concept

First Line of Defense – Barrier Islands. The coastline of mainland Mississippi is bordered on the south by the Mississippi Sound, a shallow body of water that separates the coast from four barrier islands that lie several miles to the south. These barrier islands are located along a littoral drift zone that moves sand westward creating three elongated islands and then to the westward most island where littoral currents are not as well defined. From east to west, the islands are Petit Bois, Horn, Ship, and Cat. Ship Island has been breached by prior hurricanes and now is actually two small islands, West Ship Island and East Ship Island, with a shallow sand bar between the two. Since Hurricane Camille in 1969, this breach has existed with varying amounts of natural rebuilding between later storms. The western ends of both Petit Bois and Ship Islands have migrated to maintained navigation channels and the continuing littoral drift of the sand into the channels is causing an artificial termination of the migration. A new island has emerged on the west side of the channel from Petit Bois Island, created from the dredged sand coming from island that is disposed of on the west side of the channel. Soon after Hurricane Katrina, it was reported that many in Mississippi felt that if the islands had been in the condition that existed prior to Hurricane Camille, there would have been less damage along the coast from Hurricane Katrina. This idea was also included in the Mississippi Governor's Restoration Plan, which called for restoring the islands to a pre-Camille footprint. The idea was also included in the Mississippi Governor's Restoration Plan, which called for restoring the islands to pre-Camille footprint. This measure (identified as LOD-1) was selected to be carried forward for further analysis.

Second Line of Defense – Dunes along Existing Beaches. Essentially all the beaches along coastal Mississippi are man-made. Harrison County has the most beach-front with 26-miles extending from Biloxi Bay to St. Louis Bay. Hancock County has several miles of beach and Jackson County only a short length. In total, the beaches extend along less than half of the Mississippi coastline. Most of the dunes that previously existed along these beaches were destroyed by Katrina and much of the beach was damaged. Reconstruction of the dunes, where beaches exist, will likely provide reduction of damaging wave action from smaller storms.

The beaches, as situated immediately seaward of developed areas, provide a location where elevated dunes could be constructed to provide some protection from smaller hurricanes. This measure (identified as LOD-2) was selected to be carried forward for further analysis. First concepts would look at crest elevations of 10.0 and 15.0 feet above sea level (NAVD-88) as options for the all dunes.

Third Line of Defense – Raised Roadway or Seawall and Ring Levees. All of the beaches described in LOD-2 have a roadway landward (North) of the beach. These roads vary from local or county roads to US Highway 90, a major, four-lane, highway that extends across the entire Harrison County coast. The existing roadways vary in elevation from four to five feet above sea level (NAVD-88) in Jackson and Hancock County and up to about 15 feet above sea level in Harrison County. All

of these roads are evacuation routes and all have been damaged in past hurricanes. In a damaged or destroyed condition, these roads make re-entry to the area difficult after a hurricane has passed. Raising and using these roadways as barriers or having an associated seawall defines a portion of the 3rd line of defense (LOD-3) and will be carried forward for further analysis. This line will be the first hard engineered structure and will be initially evaluated at elevations 12.0, 18.0 and 24.0 feet above sea level and will be supplemented by nonstructural solutions such as the elevating or buying out of structures.

Fourth Line of Defense – Inland Barrier. To preserve the shoreline environment as much as possible, a 4th line of defense (LOD-4) for very large storms is envisioned that would be inland from the coast (and LOD-3). This line of defense would be the highest line and could be designed to contain a larger storm surge, such as the "Maximum Possible Intensity" (MPI) hurricane, and will also be supplemented by nonstructural solutions such as the elevating or buying out of structures. This line of defense was selected to be carried forward for further analysis. First efforts would model LOD-4 as an infinitely high barrier against storms varying from a Camille type storm up to the MPI.

Fifth Line of Defense – Maximum Surge Limit. This line of defense will be a line on a map that indicates the extent of surge resulting from the "Maximum Possible Intensity" storm. Structures that are situated or built above (North of) this line should not be inundated from surge by large storm events. This fifth line of defense (LOD-5) was selected to be carried forward for further analysis. Initial efforts would look at nonstructural plans to either build future or relocate existing emergency services such as hospitals, or police and fire stations.

The following figures (12 - 14) indicate the initial alignments of the lines of defense concepts.

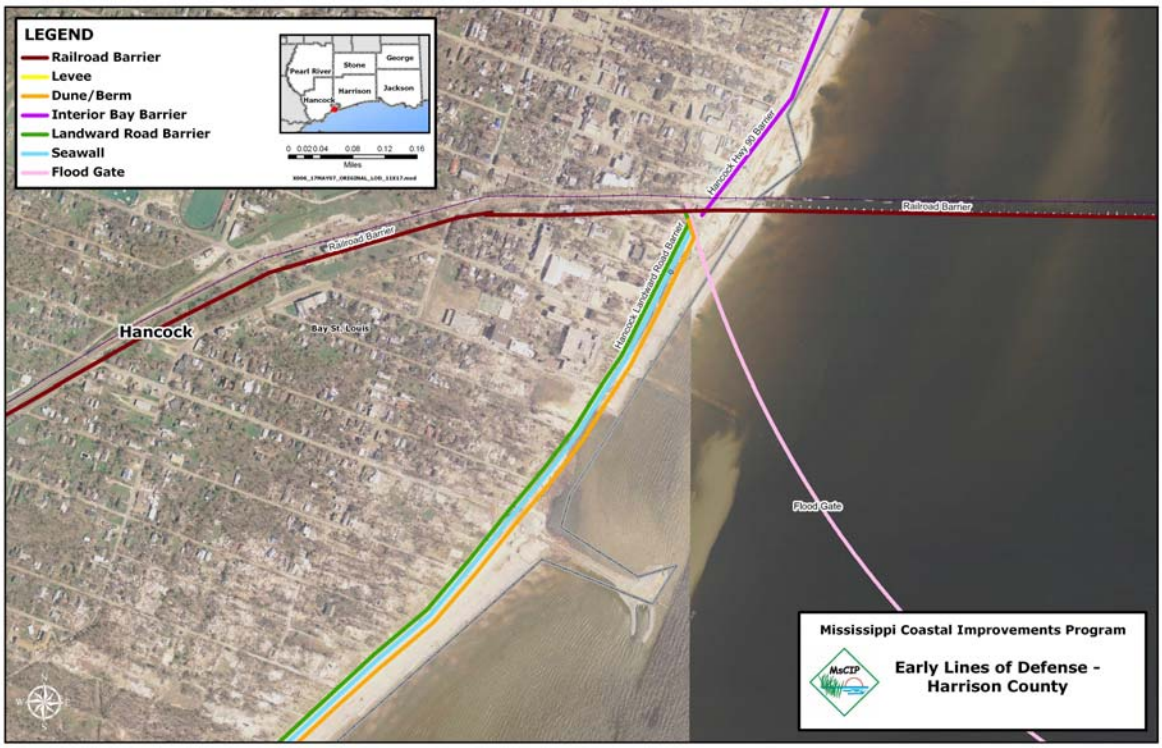

Figure 12 Initial Lines of Defense for Hancock County

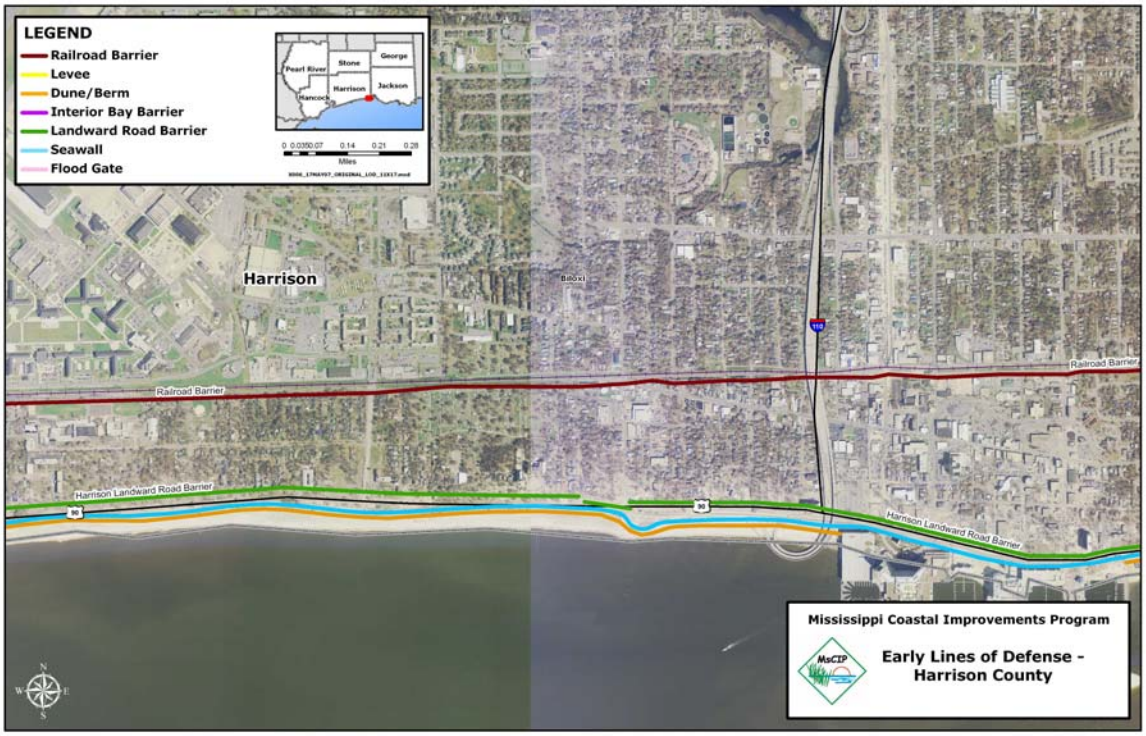

Figure 13 Initial Lines of Defense for Harrison County

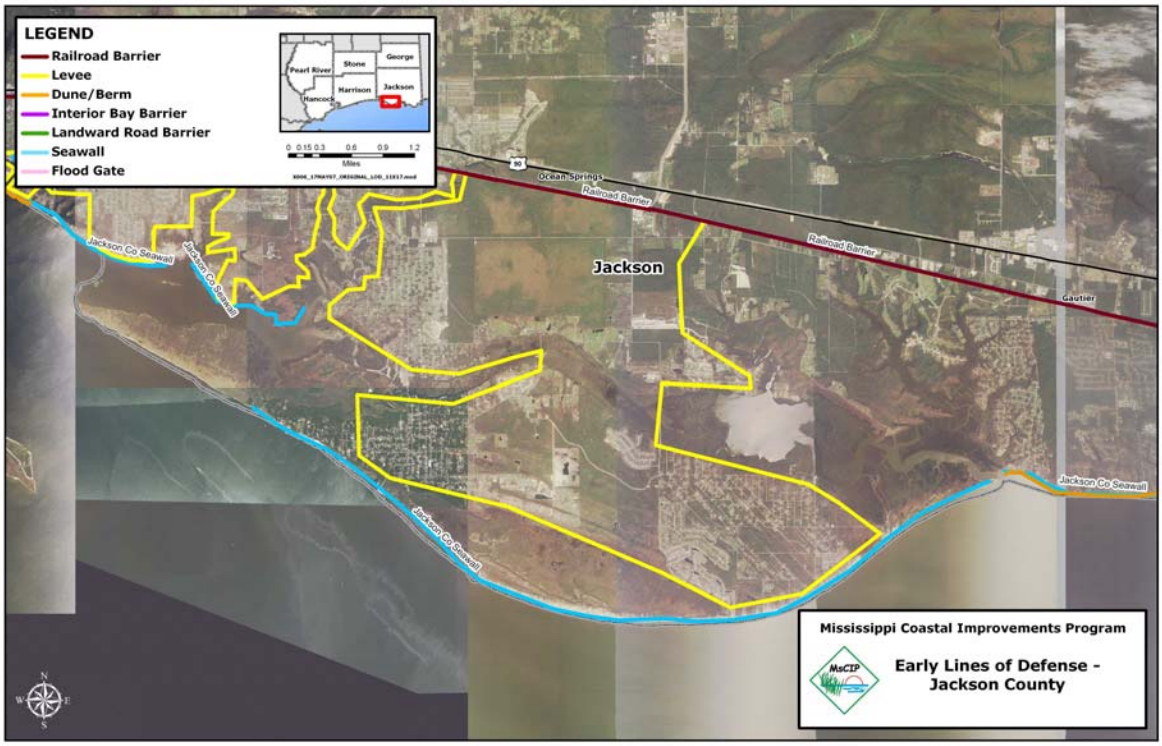

Figure 14 Initial Lines of Defense for Jackson County

Due to the relatively low elevations, type of construction, and the nature of storm surge throughout the coastal area, several preliminary nonstructural measures were also screened from further evaluations. These include:

- Elevating structures on fill material
- Dry floodproofing of residential structures (maximum protection is 3 feet), and
- Wet floodproofing of residential structures (elevating utilities)

Additional information on these measures can be found in the Engineering, Environmental, and Nonstructural Appendices.

7 RISK ASSESSMENT AND EDUCATION IN PLAN FORMULATION

7.1 Intro to Risk

The additional process of evaluating and appropriately integrating risk, uncertainty and consequences of potential actions in the plan formulation process used the following criteria of: a) identification, b) quantification, and c) characterization, of these factors. This process is summarized below.

7.1.1 Risk in Identification in Technical Analyses

Risk identification involved the selection of various parameters around which risk might be quantified. The first level of risk identification involved the selection of those parameters, by agreement of the study team, technical experts, and appropriately-trained risk-educated staff brought in to assist in this process, from the Corps Engineering Research and Development Center (ERDC).

Risk was initially identified for certain technical parameters, including stage (the depth to which water could rise during a surge event), frequency, wave height, first floor elevation of structures, structure value, and content value. Uncertainty was also accommodated by the evaluation of multiple storm tracks (paths), magnitudes (strength), and alignments, to ensure that the maximum number of potential conditions was incorporated into the assumptions that went into defining future without-, and with-project conditions.

7.1.2 Risk Identification in the Planning Process

In addition, to risks and uncertainties in technical parameters, numerous other factors were also identified as having the potential for risk, uncertainty, or consequences. These included risks associated with the potential for impacts to culture and historical properties, public service disruption, risk associated with long-term sustainability of measures, risk, uncertainty and potential consequences to individuals and families, and other societal issues.

Identification of factors that required assessment also included the definition of a unit of measure (or "metric") by which the factor would be judged, such as measuring risk of being off on an estimate of inundation depth by how many feet above or below the expected depth the technical expert could

consider that value to vary for a given storm; another example could be the amount of money that a damage estimate might vary for a given storm event.

Input on the factors found to be of most importance to the public and decision-makers was sought at public workshops set up to establish *which factors* were of importance, and also get input on which factors they found of *highest* importance. A full discussion on the selection of risk "metrics" and their discussion and selection by the public, is contained in the appendix on the RIDF process.

7.2 The Risk-Informed Decision Framework (RIDF) Process

The first step in the planning process is determining the problems, opportunities, and objectives which guide the study team in developing solutions. The next step involving risk is to structure the objectives using a hierarchical approach. For example, the study team considers many different risks associated with a flood event in an effort to develop and implement measures to minimize damages cause by storm surge. Residual risk is that portion of the total sum of all risks that still exists after a flood damage reduction project is implemented. Therefore, the overall objective guiding the selection of measures could be expressed as minimizing the residual risk from storm surge in terms of the economic, environmental and societal consequences associated with a flood event. This overall objective might be further divided into its component, or sub-objectives (i.e. - economic, environmental, and societal). These sub-objectives are incorporated into the planning process through measurable metrics that are used to compare the performance of each measure in an economic context (e.g., cost effectiveness), an environmental context (e.g., preservation of fish and wildlife habitat for ecological stability), or a social context (e.g., societal displacement). Successful planning requires giving careful attention to clearly describing and structuring the objectives for the study in detail. The next step involves developing metrics to represent the objectives. These metrics will then be used to calculate performance scores and ranks for the measures during the evaluation and comparison steps of the planning process.

7.2.1 Risk "Metric" Development

The MsCIP team developed metrics to be used in evaluating measures to accomplish the study objectives. If a measure did not meet the performance goals, it would either be screened out (dropped from further consideration) or taken back to the "drawing board" for refinement. The metrics themselves would be scored (or weighted) and ranked by various stakeholder groups, which would in turn aid decision makers in identifying a plan or plans to be recommended for implementation.

Evaluating measures by a large set of metrics can be complex and very time consuming. With this in mind, the study team selected an effective set of metrics that, while representing the best available information, would not be so large as to hinder the evaluation process.

The following criteria were used in selecting metrics to insure that they were:

- Scientifically verifiable. Meaning that two independent assessments would yield similar results.
- Cost-effective. The technology required to generate data for the metrics is economically feasible and does not require an intensive deployment of labor.
- Communicable. Are easy to communicate to a wide audience. The public would understand the scale and context, and be able to interpret the metric with little additional explanation.

- Changeable by human intervention. The metric would describe a dependent relationship between the outcome of the measure and those things that are under a decision-maker's control. Metrics that are independent of human action does little to help evaluate a measure.
- Credible. It would be perceived by most stakeholders as accurately measuring what it is intended to measure.
- Scalable. It would be directional in nature, whether qualitative (best, good, worst) or quantitative (dollars, acres, percent damaged), as appropriate.
- Relevant. It would reflect the priorities of the public and other stakeholders and enhance their ability to execute their stewardship responsibilities. There is no point assembling a metric no one cares about.
- Sensitive. The metric must be able to capture the minimum meaningful level of change, make the smallest distinctions that are still significant, and any uncertainty about the metric is easy to communicate.
- Minimally redundant. What the metric measures is not essentially reflected by another metric.
- Transparent. The use and development of the metric is readily apparent.

It is important to acknowledge here that there will be "conflicts" among metrics, resulting in the need to make tradeoffs. For example, a tradeoff exists between achieving any significant benefit from a project and minimizing cost. As a consequence of such "conflicts", a given measure may not take clear precedence over other measures in respect to every "metric" for evaluating performance. This may present a dilemma to decision-makers, who are trying to choose a single measure. It is important to place development of metrics prior to the development of measures because the "hard thinking" that goes into developing the metrics can create an improved set of measures. This permits stakeholders to focus on thinking about the objectives rather than anchoring themselves to their "favorite" measures.

Within a particular scenario, the amount of uncertainty surrounding metric values must be clarified. Metric values depend upon either a mathematical model, empirical data from a study, or expert opinion. All of these sources share varying degrees of uncertainty, presumably more so for expert opinion than for models and studies. Therefore, along with indicating the basic source of the metric values, it is also necessary to describe the assumptions that went into calculating the value. Estimates of the uncertainty for a metric should be quantified (e.g., in terms of the variance or range associated with the estimate). This quantification must be captured and integrated into the decision analysis in order to make risk-informed decisions.

An initial set of metrics were developed by the study team and then shared with several "focus" groups". They in turn helped to shape the final list of metrics, described and grouped by different accounts below.

Environmental Quality (EQ) Metrics

1) Tidal Habitat Restored - This metric measures (in acres) positive changes to the tidally-influenced wetlands that results from the implementation of a measure or plan. These are positive benefits from implementing a restoration plan or a combination of plans. Ecosystem components included in this metric are tidal wetlands (i.e., tidal fringes), associated threatened and endangered (T&E) and other species, associated essential fish and other tidal habitats (i.e. oysters, submerged aquatic vegetation), and related losses that require mitigation due from implementation of structural plans. There are 5 tidal wetland functions measured: wave energy attenuation (wave energy absorbed by wetland through landscape position, marsh width, and vegetation cover), biogeochemical cycling (receive, transform, and export nutrients through a wetland), nekton (swimming organisms)

utilization potential (whether wetland contains suitable habitat for nekton), provide habitat for tidal marsh dependent vertebrate wildlife, and maintain a characteristic tidal marsh plant community. Units for this metric are the percentage increase of quality fish and wildlife habitat in functional habitat units (FHI).

2) Tidal Habitat Lost - This metric measures adverse impacts to the tidally-influenced wetlands that results from the implementation of a measure or plan. Ecosystem components included in this metric are tidal wetlands (i.e., tidal fringes), associated threatened and endangered (T&E) and other species, associated essential fish and other tidal habitats (i.e. oysters, submerged aquatic vegetation), and related losses that require mitigation due from implementation of structural plans. There are 5 tidal wetland functions measured: wave energy attenuation (wave energy absorbed by wetland through landscape position, marsh width, and vegetation cover), biogeochemical cycling (receive, transform, and export nutrients through a wetland), nekton (swimming organisms) utilization potential (whether wetland contains suitable habitat for nekton), provide habitat for tidal marsh dependent vertebrate wildlife, and maintain a characteristic tidal marsh plant community. Units for this metric are also in acres.

3) Non-tidal Habitat Restored - This metric measures (as functional units) positive changes to the non-tidal ecosystem that result from the implementation of a measure or plan. These are positive benefits from implementing a restoration plan or a combination of plans. Ecosystem components included in this metric are maritime forests, beach nourishment, dune restoration and vegetation, and associated threatened, endangered and other species in non-tidal habitats. There are numerous functions provided by upland habitat: wildlife and birds (includes threatened and endangered species) roosting, nesting, and foraging utilization potential, wildlife corridors, sustainability of the Mississippi Flyway, restoration of the natural ecology and aesthetics of the area, and maintenance of plant community composition. Units for this metric are the percentage increase of quality fish and wildlife habitat in acres.

4) Non-tidal Habitat Lost- This metric measures (as functional units) adverse impacts to the non-tidal ecosystem that results from the implementation of a measure or plan. This has a negative impact of implementation of an array of alternatives as part of the comprehensive plan. Ecosystem components included in this metric are maritime forests, beach and dunes, threatened, endangered and other species and their non-tidal habitats, and related losses that require mitigation due to implementation of structural plans. There are numerous functions provided that will be evaluated and include: breaks in natural wildlife corridors, fragmentation of habitat, loss of critical habitat for threatened and endangered species, loss of foraging and roosting areas, loss of vegetation resulting in increased erosion, reduction in water quality and air quality. Units for this metric are the percentage decrease of quality fish and wildlife habitat in acres.

National Economic Development (NED) Metrics

5) Monetary Damages Reduced/Avoided (Expected Annual Damages) - The amount of storm damages reduced/avoided by a plan expressed as annualized dollars. Annualized dollars are calculated by comparing a future without a project in place versus a future with a project in place. Damages are calculated by using the Hydrologic Engineering Center-Flood Damage Analysis (HEC-FDA) model. This metric has become standard practice in the evaluation of the value of measures with respect to estimating damages to assets (i.e., residential, commercial, and industrial infrastructure and their contents) over the period of analysis. For more detail about the HEC-FDA model see Economics Appendix.

6) Residual Damage – This metric describes what a plan does not account for (or what happens if a plan is exceeded). Residual damage is defined as the storm damage that is not prevented with the implemented plan in place (expressed as annualized dollars).

7) Cost to Implement Plan – The amount of money in dollars needed to implement the plan. This metric measures the cost in today's dollars to local and Federal governments to implement the recommended plan.

Other Social Effects (OSE) Metrics

These metrics focus on the preservation of people's quality of life. OSE metrics were developed to address impacts to cultural heritage and preservation of historical structures, disruptions to public service and infrastructure and impacts to personal effects.

8) Cultural and historical heritage impacts – This metric addresses impacts to social groups, church congregations, and groups with common heritages. This metric also includes impacts to aesthetics and the destruction of the human-created landscape such as historical structures. The units for this metric will be a unitless quantitative scale (0-10). A score of 10 is best, 1 is bad.

9) Public service and infrastructure disruptions – This metric includes disruptions to schools, fire and police service, access to hospitals, libraries and community centers, and use of roads, bridges, and utilities. The units for this metric will be a unitless quantitative scale (0-10). A score of 10 is best, 1 is bad.

10) Personal impacts – This metric includes loss of family possessions, photographs, and impacts to people's emotional and mental health. The units for this metric will be a unitless quantitative scale (0-10). A score of 10 is best, 1 is bad.

Regional Economic Development (RED) Metrics

The RED metrics measure both positive and negative impacts to the regional economy. Positive impacts are captured by impacts to sales volume, personal income and employment and negative impacts by local cost burdens. Sales volume, income and employment will be sub-metrics under RED, and will be equally weighted. This metric is termed Positive regional economic benefits and will combine these 3 sub-metrics. The local cost burdens metric is also a sub-metric under RED and will receive a weight equal to combined weighting of the positive metrics under regional economic benefits.

11) Local Cost Burdens – This metric represents the costs and burdens to the local governments due to implementing a measure. This includes cost-sharing requirements with the Federal government to implement the plan and local costs for ongoing operations and maintenance (O&M) related to the implemented plan. The local cost burdens may also include those associated with additional workforce needed to maintain features of an implemented plan. This metric will be based on a unitless quantitative scale (0-10). A score of 10 is best, 1 is bad.

12) Positive regional economic benefits – Economic benefits to the region with regards to sales volume, income and employment. This metric was evaluated using the economic impact forecasting system (EIFS) model. This model is an economic analysis tool that given the inputs for a particular plan will assess potential impacts of sales volume change and personal income in dollars and regional employment change in number of jobs to the local economy. Uncertainty will be based on several factors such as population, implementation cost, and social behavior of people in the region. This metric will be based on a unitless quantitative scale (0-10). A score of 10 is best, 1 is bad.

Risk Metrics

The following risk metrics serve as additional information to decision makers. They are a way to address extreme cases of uncertainty.

13) Long-term Sustainability of Plan – The risk that features associated with the recommended plan will not perform as intended (over time) due to factors such as cost, human behavior, technical level

of maintenance required, political concerns, resource availability, local funding per year, and operational reliability. The units for this metric will be a unitless quantitative scale (0-10). A score of 10 is best, 1 is bad.

14) Residual Risk – This metric describes what a plan does not account for (or what happens if a plan is exceeded). Residual risk is defined as the storm damage risk that remains with the implemented plan in place (expressed as annualized dollars). It accounts for the following factors: erosion, wildlife species, wildlife habitat, salt water intrusion, surge damages, drainage, wind, maximum probable intensity (MPI) plan (accounts for more intense storm), cultural heritage, and infrastructure. The units for this metric will be a unitless quantitative scale (0-10). A score of 10 is best, 1 is bad.

15) Consequences of Plan Failing – This criterion describes what happens if a plan does not work as intended. In other words, it describes consequences to humans and the environment due to a catastrophic failure of an implemented plan under design conditions or other sets of circumstances from a storm event. The greatest risk is risk of failure to structural measures, such as levees, flood gates, etc. Consequences and likelihood of failure vary depending on the line of defense. For example, risk of Line 2 failure is more likely, but consequences are relatively low; risk of Line 4 failure is highly unlikely, but consequences are very high. It includes the following factors: injuries to population, loss of infrastructure, loss of habitat, and loss of wildlife species. The units for this metric will be a unitless quantitative scale (0-10). A score of 10 is best, 1 is bad.

Once the 15 metrics were described, the study team developed the values associated with each measure. The team calculated the acres associated with each measure for the metrics within the Environmental Quality Account as discussed above. The NED metrics were developed through the use of the Corps' HEC-FDA program (further described in the Economics Appendix) and are expressed in dollars.

As mentioned above, the RED, OSE, and Risk metrics are based on a scale from 1-10. Guidelines for these metrics were given to the team to help provide consistency amongst the different measures and are defined in the following tables.

Table 20.

Regional Economic Development Scoring Definitions

Score	Local Cost Burdens	Regional Economic Benefits
1	All Local Government funds are exhausted to cover the cost-shared portion, an extremely large workforce must be hired to perform maintenance of plan features, and the plan results in increased support of the area infrastructure.	Little or no economic benefits, or increase in sales volume, income and employment to the region.
2	A very large percentage of local funds would be required for cost-share and a very large workforce must be hired to perform maintenance of plan features. The plan results in a large burden on local government to support the area infrastructure.	Very small economic benefits, and increases in sales volume, income and employment to the region.
3	A large percentage of local funds would be required for cost-share and a large workforce must be hired to perform maintenance of plan features. The plan results in a large burden on local government to support the area infrastructure.	Minor economic benefits, and increases in sales volume, income and employment to the region.
4	A significant percentage of local funds would be required for cost-share and maintenance support of plan features. Plan also puts a significant burden on local governments to maintain infrastructure.	Some economic benefits, and increases in sales volume, income and employment to the region.
5	A moderate percentage of local funds are required	Moderate economic benefits, and increases in sales

Score	Local Cost Burdens	Regional Economic Benefits
	for cost-share and maintenance support of plan features. Plan puts moderate burden on local governments to maintain infrastructure.	volume, income and employment to the region.
6	Some local funds are required for cost-share and maintenance support of plan features. Plan puts mild burden on local governments on infrastructure.	Significant economic benefits, and increases in sales volume, income and employment to the region.
7	A minor percentage of local funds are required for cost-share and maintenance support of plan features. Plan also puts a minor burden on local governments to maintain the infrastructure.	Large economic benefits, and increases in sales volume, income and employment to the region.
8	A very small percentage of local funds will be required for cost-share and maintenance support of plan features. Plan puts mild burden on local governments to maintain the infrastructure	Very large economic benefits, and increases in sales volume, income and employment to the region.
9	Extremely small disruption to local funding, infrastructure, or maintenance support of plan.	Extremely large economic benefits, and increases in sales volume, income and employment to the region.
10	No burden on Local Government to cost-share, operate and maintain plan features, or support infrastructure.	Tremendous economic benefits, and increases in sales volume, income and employment to the region.

Table 21

Other Social Effects Metric Scoring Definitions

Score	Cultural & Historical Heritage	Public Service Disruptions
1	Total Loss of Community and Cultural and Historical Heritage.	All Public Services are interrupted and are interrupted during all events that currently affect them; no police or fire service or schools that would be affected would be available; hospitals, libraries, etc., would remain closed indefinitely. Roads, bridges, utilities, and other infrastructure destroyed.
2	A portion of community exists but much of what is culturally and or historically significant would continue to be lost.	Significant Disruptions that last for weeks to months. Measure may provide a very small measure of improvement.
3	A portion of community exists but most of the Cultural and Historical Significance is lost.	Severe Interruptions to Public Services. Significant amount of damage to roads, bridges, and utilities.
4	Significant Losses, or Changes to - - - Historical Setting (i.e Aesthetics – view, Loss to Community Defining Landmarks and/or Structures, Change in Land Use (i.e : A complete change in how they use their community)	Very limited public services would still be provided. Hospital offers emergency services. Schools and other services may close. Road and Bridges damaged and could remain closed for moderate amount of time.
5	Moderate Loss to, or Change to Historical Setting (i.e Aesthetics – view, Loss to Community Defining Landmarks and/or Structures, Change in Land Use (i.e : An almost complete change in how they use their community)	Limited public services provided. Small portion or number of hospitals are able to operate. Schools and other services remain closed. Road and Bridges damaged but most are usable in a few weeks.
6	Low Chance of Loss to, or Change to Historical Setting (i.e Aesthetics – view, Loss to Community Defining Landmarks and/or Structures, Change in Land Use (i.e : Almost complete change in how they use their community)	Mild Disruption to public services. Most everything back to normal operations within 7 days
7	Divide Community Cohesiveness – Community still exists but functions separately. Some of cultural and historical essence and features are lost, but community may still retain some of what makes it culturally and historically significant.	Minor Disruption to public services. Most everything back to normal operations soon after the event.
8	Community Still Functions and retains Cultural and Historical Heritage Significances but Notable Changes are Be Community Still Functions and retains Cultural and Historical Heritage Significances but Subtle Changes may occur that do impact community integrity.	Very minor disruption to public services. Most everything back to normal operations soon after the event.

Score	Cultural & Historical Heritage	Public Service Disruptions
9	Community Still Functions and retains most Cultural and Historical Heritage Significance; There may be small, subtle changes.	Extremely small disruption to public services. All services back to normal operations within days.
10	Complete Preservation of Community values, historical significance, and cultural heritage.	No impacts to normal way of life. Virtually no impacts to public services.

Table 22.

OSE / Risk Metric Scoring Definitions

Score	Personal Impacts	Long-Term Sustainability
1	Total Loss of Family Possessions due to Continued Hurricane Occurrence or to Plan Implementation (i.e. Property and Livelihood, Irreplaceable Items, Sense of Security, Mental Stability & Emotional Well-being) – Everyday Life no longer exists - Numerous Persons would be affected by events and might require professional therapy; most persons would likely not overcome effects of events	Complete failure (lack of sustainability) of plan (i.e. - will not perform as intended (over time) due to factors such as cost, human behavior, technical level of maintenance required, political concerns, resource availability, local funding per year, and operational reliability), is a certainty, at some time within period of analysis.
2	Majority of Family Possessions Lost (i.e. Property and Livelihood, Irreplaceable Items, Sense of Security, Mental Stability & Emotional Well-being) – Everyday Life no longer exists - Numerous Persons would be affected by events and might require professional therapy; many persons would likely not overcome effects of events	Will almost certainly fail within lifetime of project due to some factor associated with sustaining the plan. The plan will likely not be politically supported for funding or be reliably and fully maintained during its intended project life. Human behavior will almost certainly interfere with project performance sometime during project life, very high technical level of maintenance will be required, and very high risk that plan will not be operated correctly during time of need.
3	Significant Amount of Family Possessions Lost (i.e. Property Severely Damaged, Livelihood Significantly Changed, Many Irreplaceable Items Lost, Sense of Security, Mental Stability & Emotional Well-being Significantly Altered – Everyday Life no longer exists - Many people would be affected by events and could require professional therapy; many would likely not overcome effects of events for a very long time	Plan failure highly likely within project life. Minimal political support and project sustainability highly unlikely (i.e. maintenance and funding). Human behavior will interfere with project performance sometime during project life, high technical level of maintenance will be required, and high risk that plan will not be operated correctly during time of need.
4	Moderate Amount of Family Possessions Lost (i.e. Property Damaged, Livelihood Changed, Some Irreplaceable Items Lost, Sense of Security, Mental Stability & Emotional Well-being Shaken – Everyday Life Changed - Many people would be affected by events and might require professional therapy; a significant number of people would likely not overcome effects of events; some would benefit from professional therapy	Plan could possibly fail within project life. Minimal political support resulting in reduced funding and/or maintenance abilities. Human behavior may negatively affect project performance, moderate technical level of maintenance is required, and moderate risk of plan not being operated correctly.
5	Some loss of personal possessions remains likely over period of analysis; livelihood may be changed; irreplaceable items might be lost; some loss of security; property damages do affect one's sense of well-being; life for most could be altered; some loss of family possessions remains likely	Plan should perform as intended over entire project life, but possibility exists that it would not be sustained. Plan may not get sufficient political support for either sustained funding or maintenance over the life of the project. Human behavior may negatively affect project performance, moderate technical level of maintenance is required, and moderate risk of plan not being operated correctly.
6	Some loss of personal possessions is somewhat likely over period of analysis; livelihood could be changed at some point; irreplaceable items could be lost; some would suffer from loss of security; property damages could potentially affect one's sense of well-being; life for some would be altered at some point;	Plan will likely perform as intended over entire project life. There is general political support to implement the plan, but there is a risk of funding and maintenance being interrupted over project life. Negative human behavior may have some effect on project performance, and technical maintenance is required. There is also a moderate risk of the plan not being operated correctly.
7	Some loss of personal possessions could happen during period of analysis; chance exists that livelihood could be changed; irreplaceable items could be lost, but chance	Plan will most likely perform as intended over entire project life. There is general political support to implement the plan, but there is a moderate risk of

Score	Personal Impacts	Long-Term Sustainability
	is not good; some might suffer from loss of security, but although shaken, overall emotional well-being is good for vast majority of period of analysis; property damages affecting one's sense of well-being is not likely; life for small number of people could be altered at some point; Family Possessions could be impacted but most would be recoverable.	funding and maintenance being interrupted over life of project. Negative human behavior has some effect on project performance, and a moderate level of technical maintenance is required. There also remains some risk of the plan not being operated correctly.
8	Some loss of personal possessions could happen during period of analysis; small chance exists that livelihood could be changed; irreplaceable items have low likelihood of being lost; sense of security would not be shaken for vast majority, overall emotional well-being is good to very good; property damages affecting one's sense of well-being is highly unlikely; Family Possessions might be impacted, but most would be recoverable.	Plan is very unlikely of not performing as intended over entire project life. There is general political support, but some issues could arise causing delay to fully implement the plan. There is low risk of funding and maintenance being interrupted over life of project. Negative human behavior has some effect on project performance, a low to moderate level of technical maintenance is required, and there is a low to moderate risk of plan not being operated correctly.
9	Very low likelihood that loss of personal possessions would happen during period of analysis; chance exists that livelihood could be changed; irreplaceable items could be lost, but chance is extremely unlikely; very few would suffer from loss of security; overall emotional well-being is very good to excellent for vast majority of period of analysis; property damages affecting one's sense of well-being is extremely unlikely; life for very small number of people could be altered at some point; family possessions impacted but most recoverable; Recovery is Immediate.	Plan will almost certainly perform as intended over entire project life. There is strong political support and will to implement the plan, and an extremely low risk of funding and maintenance being interrupted over life of project. Negative human behavior would have extremely low likelihood of having any effect on project performance, an extremely low technical level of maintenance is required, and an extremely low risk of plan not being operated correctly.
10	Complete preservation of family possessions (i.e. Property and Livelihood, Irreplaceable Items, Sense of Security Mental Stability & Emotional Well-being)	Plan will absolutely perform as intended over entire project life. It is fully politically supported, resources are more than adequate to maintain the project, human behavior will not negatively affect project performance, minimal to no maintenance required, extremely low risk of funding being interrupted, and extremely low risk of plan not being operated correctly.

Table 23

Risk Metric Scoring Definitions

Score	Consequence of Plan Failing	Residual Risk
1	Plan failure would result in extremely widespread and extensive injuries and large number of deaths; enormous number of structures destroyed, and almost all of remainder damaged significantly; community would suffer total loss of infrastructure; wildlife would suffer severely as result of plan failure; habitat loss would be extreme as result of plan failure	Tremendous residual risk; All or almost all damages and risks remain unaddressed; Risks of continued damage to ecosystems, infrastructure, erosion or saltwater intrusion remain unabated; threats to cultural or historical heritage remain extremely high.
2	Plan failure would result in extremely widespread injuries and significant number of deaths; Very large number of structures destroyed, and most of remainder damaged significantly; total infrastructure loss, wildlife, and habitat loss throughout Coastal Mississippi	High to extremely high residual risk; almost all damages and risks remain unaddressed; risks of continued damage to ecosystems, infrastructure, erosion or saltwater intrusion remain unabated; threats to cultural or historical heritage remain very high.
3	Plan failure would result in widespread injuries, large number of deaths, and large number of structures destroyed, with many of remainder damaged; significant damage to infrastructure, and loss of wildlife; widespread habitat damage or loss would occur	High residual risk; vast majority of damages and risks remain unaddressed; risks of continued damage to ecosystems, infrastructure, erosion or saltwater intrusion remain high; threats to cultural or historical heritage remain high, and cultural heritage could be severely compromised.
4	Very numerous people would be injured; moderate to large number of deaths; fairly large number of structures destroyed, and some of remainder damaged	Moderate to high residual risk; majority of damages and risks remain unaddressed; risks of continued damage to ecosystems, infrastructure, erosion or saltwater

Score	Consequence of Plan Failing	Residual Risk
	significantly; loss of infrastructure would be moderate to highly significant; much wildlife would be impacted; habitat damage or loss would be moderate to highly significant	intrusion remain high; threats to cultural or historical heritage remain moderate to high, and cultural heritage could be compromised.
5	Numerous people could be injured; moderate number of deaths; fair number of structures destroyed, and some of remainder damaged; loss of infrastructure would be moderate, but would require significant amount of time for recovery; wildlife would be impacted, but much would recover; habitat damage or loss would be moderate	Moderate residual risk; much of damage and risks remain unaddressed; risks of continued damage to ecosystems, infrastructure, erosion or saltwater intrusion remain moderate, but for a significant number, risk is reduced; threats to cultural or historical heritage remain moderate, and little of cultural heritage would be compromised. Environmental habitat could suffer but most could be restored with minor effort.
6	Moderate to minimal number of injuries as a result of plan failure, small to moderate number of deaths; some structures destroyed, and some number of remainder damaged; still substantial potential impacts to infrastructure, but much would recover quickly; habitat damage or loss would be moderate to small	Small to moderate residual risk; some of damage and risks remain unaddressed; risks of continued damage to ecosystems, infrastructure, erosion or saltwater intrusion are at small to moderate risk, but significant amount of risk is reduced; threats to cultural or historical heritage would be small to moderate, and very little risk of cultural heritage being compromised. Environmental habitat could suffer but most could be restored with very little effort.
7	Minimal number of injuries as a result of plan failure, small number of deaths might result; small number of structures destroyed, some damaged; moderate potential impacts to infrastructure, but almost all would recover quickly; habitat damage or wildlife loss would be small, and could recover quickly, impacts to infrastructure would be minimal, and recovery of most would be rapid	Small amount of residual risk; some damage and risks remain unaddressed; risks of continued damage to ecosystems, infrastructure, erosion or saltwater intrusion are at small risk, but most risk is reduced; threats to cultural or historical heritage would be small, and almost no risk of cultural heritage being compromised. Limited risk of environmental habitat suffering, and that which did would be restored with very little effort.
8	Very small number of injuries would occur as a result of plan failure, very small number of deaths; minimal number of structures damaged or destroyed; minimal potential impacts to infrastructure, and almost all would recover quickly; habitat damage or wildlife loss would be very small, and would recover quickly, impacts to infrastructure would be minimal, and recovery of majority would be rapid	Very small amount of residual risk; very limited amount of remaining risk or potential damages would remain unaddressed; risks of continued damage to ecosystems, infrastructure, erosion or saltwater intrusion are at very small risk; vast majority of risk is reduced; threats to cultural or historical heritage would be very small, and cultural heritage at very low risk of any compromise. Very limited risk of any environmental habitat suffering over project life, and that which did would be restored with very low effort.
9	Extremely small number of injuries would occur as a result of plan failure; Few to no deaths would result; very small number of structures, if any, destroyed, and small number of remainder damaged; minimal impacts to infrastructure, and all would recover quickly; habitat damage or wildlife loss would be extremely small, and would recover quickly; and recovery of majority would be rapid. No Injuries, very minimal infrastructures, wildlife, and habitat impacts	Extremely small amount of residual risk; extremely limited amount of remaining risk or potential damages would remain unaddressed; risks of continued damage to ecosystems, infrastructure, erosion or saltwater intrusion are at extremely small risk; almost all risk is reduced; threats to cultural or historical heritage would be extremely small, with cultural heritage at almost no risk of compromise. Extremely limited risk of any environmental habitat suffering over project life.
10	Complete Performance of Plan No Impacts due to Failure	Almost no residual risk would remain unaddressed; risks of continued damage to ecosystems, infrastructure, erosion or saltwater intrusion are almost non-existent; threats to cultural or historical heritage would be almost non-existent, with cultural heritage at no risk of temporary or permanent compromise. Almost no risk of any environmental habitat suffering significantly over project life.

Using these definitions, the planning team starting developing metrics for the different measures. These metrics were used to help refine the measures.

7.3 "Weighting" of Risk metrics by Stakeholders of coastal Mississippi

Three sequential "risk weighting" workshops were held in July, September, and December of 2007 with various stakeholder groups. The first workshop was used primarily to make sure that the stakeholders understood the RIDF process and that the metric definitions were sound and easily understood. At this workshop, the stakeholders were subjected to two different weighting (or scoring) techniques and their feedback helped to refine the process. This process was repeated at the September workshop, where the stakeholders used example metric data to aid their understanding of the measures. Again, feedback from this workshop allowed the team to finalize the weighting process and in the December, the stakeholders were able to see the actual data for the metrics associated with the final list of alternatives. The MsCIP weight elicitation workshops yielded 45 complete sets of weights on fifteen metrics. These initial weights were used to establish the importance of each factor as determined by the stakeholders, and are shown in Table 24. An exploratory data reduction technique called a cluster analysis was used to group stakeholders with similar preference patterns expressed through their allocation of weights to metrics. These results, as shown in Figure 15, enabled the MsCIP team to compare the different stakeholder preferences that exist for potential solutions. A more detailed description of how the weights of these metrics were developed can be found in the RIDF Appendix.

Table 24.

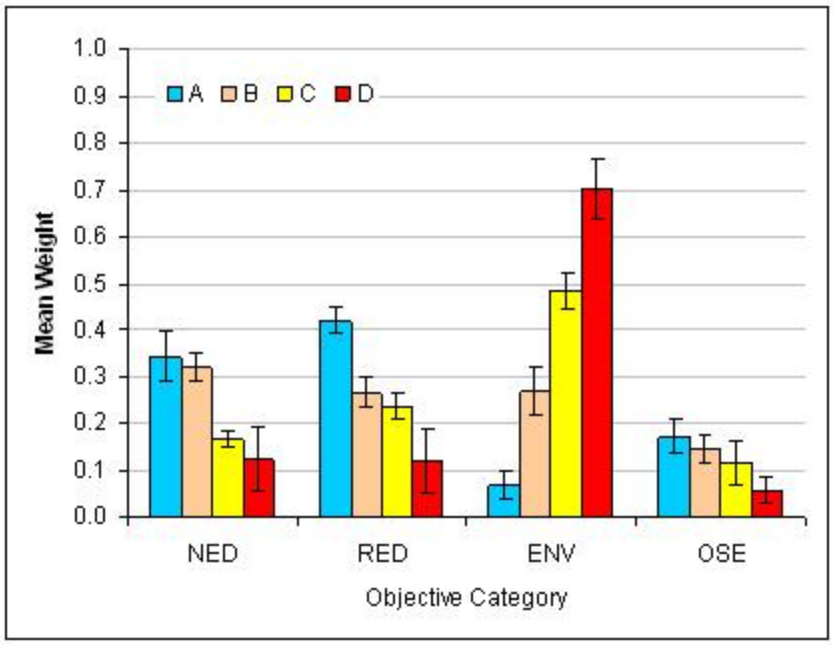

Figure 15. Stakeholder Weights for Clusters by Planning Objective

8 FORMULATION ROUND TWO

The refinement of measures consisted of modifying measures to achieve higher desired outputs (better benefits, more damage reduction, more ecosystem benefit), and to better serve the original intended purpose, based on feedback from modeling efforts or better data availability. This refinement process also included the development of data at a higher level of detail on remaining measures, and the development of data on additional areas of concern, such as cultural and environmental effects, for technical considerations not developed in detail in the first round of measure development, and for other factors.

If all of the earlier screening criteria were met, each remaining measure for a given problem area was then forwarded on for further analysis and to be evaluated and compared at a higher level of detail, in the next phase (Round Two) of analysis. This refinement process included the development of more detail in design, cost estimation, environmental components and potential impacts, potential damages prevented, site considerations, more detailed technical requirements, source material and source area considerations, variations in materials that could be used to solve the problem in a similar way, species benefits or impacts considerations, and many other technical, environmental, or economic issues.

The list of measures developed during this round by zone are presented in Table 25 below.

Table 25.

Round 2 Measures

Name (Measures screened during this round are in red)	Description
Offshore Zone	
Deer Island Restoration	Complete Restoration of Island back to its pre-Camille footprint
Increasing Islands Footprint (Option A)	Restore islands by sand dredged from off-shore
Placing River Sand in Littoral Zone (Option B)	Restore islands by placing dredged river sand in the littoral zone
Placing Off-shore Sand in Littoral Zone (Option C)	Restore islands by placing dredged sand in the littoral zone
Creating 2 FT Island Dunes with Beach Sand (Option D)	Restore islands by shaping existing beach sand into 2' high dunes
Creating 6 FT Island Dunes with Off-shore Sand (Opt E)	Restore islands by creating 6' high dunes with off-shore sand
Barrier Island No Action	
Barrier Island Restoration to Protect MS Sound Estuary	Study to recommend optimal solution to protect the MS Sound Estuary
Emergency Ship Island Restoration	Phased Advanced Engineering and Design to protect Ft. Mass. and Estuary
Sub Aquatic Vegatation Pilot Project	Tests various methods of planting SAVs in MS Sound
MS Sound Sub Aquatic Vegatation Restoration	Restore 4400 acres of lost SAVs in MS Sound using pilot results
Coastal Zone	
Hancock 40' Dune @ Elevated Roadway (Option A)	Dune adjacent to the seawall with a 40' crest at elevation 10
Hancock 50' Dune @ Elevated Roadway (Option B)	Dune adjacent to the seawall with a 50' crest at elevation 8
Hancock 20' Dune @ Elevated Roadway (Option C)	Dune adjacent to the seawall with a 20' crest at elevation 10
Hancock 30' Dune @ Elevated Roadway (Option D)	Dune adjacent to the seawall with a 30' crest at elevation 8
Hancock Dune Option A plus sea oats (Option E)	Like option A + plantings on toe of dunes
Hancock Dune Option B plus sea oats (Option F)	Like option B + plantings on toe of dunes
Hancock Dune Option C plus sea oats (Option G)	Like option C + plantings on toe of dunes
Hancock Dune Option D plus sea oats (Option H)	Like option D + plantings on toe of dunes
Hancock 55' Dune and beach berm (Option I)	Dune w/ 55' crest at elev. 10 & beach berm on south side
Hancock Dune Option I plus sea oats (Option J)	Like Option I but with plantings on toe of berm
Coastal Beach No Action	
Comprehensive 60' wide x 2' high Dune plus sea oats (Option K)	60' wide X 2' high berm with sea oats planted on 30" centers
Harrison 40' Dune @ Elevatied Roadway (Option A)	Dune adjacent to the seawall with a 40' crest at elevation 10
Harrison 50' Dune @ Elevated Roadway (Option B)	Dune adjacent to the seawall with a 50' crest at elevation 8
Harrison 20' Dune @ Elevated Roadway (Option C)	Dune adjacent to the seawall with a 20' crest at elevation 10
Harrison 30' Dune @ Elevated Roadway (Option D)	Dune adjacent to the seawall with a 30' crest at elevation 8
Harrison Dune Option A plus sea oats (Option E)	Like option A + plantings on toe of dunes
Harrison Dune Option B plus sea oats (Option F)	Like option B + plantings on toe of dunes
Harrison Option C plus sea oats (Option G)	Like option C + plantings on toe of dunes
Harrison Dune Option D plus sea oats (Option H)	Like option D + plantings on toe of dunes
Harrison 55' Dune and beach berm (Option I)	Dune w/ 55' crest at elev. 10 above datum and add beach berm
Harrison Dune Option I plus sea oats (Option J)	Like Option I but with plantings on toe of berm
Hancock Seawall/Elevated Roadway at Elevation 11	Seawall and Elevated Beach Road to Elevation 11

8.1 Refinement of Damage Reduction Measures

During early discussion with the public, many people stated the opinion that the barrier islands could be “armored”, or otherwise modified to produce a greater damage reduction effect than their current or even pre-Camille condition. Suggestions for their modification included adding additional height or length, closing off the gaps between them, or armoring them. While some thought that this idea was not a valid means of reducing damage on the mainland, the idea had a great deal of credence among numerous residents. In fact, there is a strong feeling among many that the erosion of the barrier islands contributed to the level of damage created by Katrina. While the application of armor would not be possible (due to their environmental value and inclusion in the National Parks system), the concepts of adding additional height or length were examined, to determine what degree, if any, of surge or wave reduction the barrier islands do contribute, and what they might also contribute if restored to their former dimensions and elevation. The various configurations of the barrier islands were modeled in a sensitivity analysis and is presented in Section 2.10 of the Engineering Appendix.

In conjunction with the development of various barrier islands damage reduction modeling scenarios, a structural “Lines of Defense” concept was drafted that started with an initial (or outermost) line along the alignment of the barrier islands, progressing inland to offshore breakwaters, beaches with elevated dune systems, seawalls or elevated roads (immediately inland from the beach), levees or embankments along the shoreline, or levees on various inland alignments (Highway 90, the railroad alignment, Interstate 10).

These same “lines” could also be designed to provide an increasing level of damage reduction (by increasing height) as one progressed inland.

The “Lines of Defense” (LOD) concept was modeled using both the ADCIRC model, to determine the degree of surge height reduction, and also the Beach-FX model, which was used to determine beach behavior (primarily the erosion resulting) during a hurricane event. In addition to numerous separate “lines” (barriers to surge), additional combinations of measures were also modeled to determine the most productive package of measures.

Although all iterations of the process of creating and modifying “lines” are placed under this single section of “Round Two”, there were dozens of rounds of iteration of the LODs that occurred.

The first Line of Defense, designated as LOD-1, included restoration to a pre-Camille condition, restoration to a pre-Katrina condition, restoration to a condition equivalent to the 1920’s, and one in which additional height and length was created on each island. In 1969, Hurricane Camille caused extensive erosion on the islands and created a large breach in Ship Island. This breach began to heal from the east as the littoral drift of sand added land mass to the west end of East Ship Island. This large scale breaching occurred again during Katrina, eroding away all the sand that had collected over the previous 35 years. After Katrina, it was widely expressed that if the islands had been in a pre-Camille condition, the storm surge would have been much less along the mainland coast. This scenario was modeled to help predict what effects the islands play in storm reduction. These results are discussed in Section 2-10 of the Engineering Appendix. There are a total of seven different options included in this report covering a wide range of possible ways to mitigate erosion of the islands.

The beaches (manmade in the 1950s) that extend along much of the coast were also considered as a feature that could be modified to provide some level of protection by construction of dunes on the beaches. Other projects are underway to improve the some of the beaches and proposed projects would construct small dunes on most of the beaches. Improving on these features by adding higher dunes and/or dune vegetation was designated as LOD-2. These would not provide protection from large storms, but would be beneficial for smaller storms and would provide recreational and environmental benefits. Each of the three counties has beaches that fit this scenario for adding dunes. For each county, 11 options were considered for adding some measure of dune creation. Most of the options have versions that included adding vegetation and sand fencing as well as dunes without these features. Eight of the options in each county have the dune placed against roadways that parallel the beaches with the assumption that these roadways would be elevated as a separate measure. Each of these options have a dune crest elevation less than the adjacent roadway(possibly raised in the future under LOD-3 options) to prevent sand from constantly being blown onto the road These options have some value as protection for the road, but more value as an ecological benefit. Two other options include a stand-alone dune out on the beach that could provide some level of surge defense along with ecological benefits. Each county also has an option with a wide sand berm fully planted with sea oats, the preferred vegetation to help stabilize dunes. This option will allow the sea oats to trap wind-blown sand and naturally build a dune with time. The dune options in all three counties total 33 different measures that could be considered.

As mentioned above, another existing condition along much of the coast is roadways that coincide with the beaches. It was envisioned that raising these roadways would have minimal environmental impact and provide the first hardened barrier to surge damage. These roadways, while not continuous along the coast, were designated as LOD-3. The new road elevations would not be as high as to act as a seawall for very large storms, but like LOD-2, they would be beneficial for smaller, more frequent storms. While different elevations were initially considered for the roadways, the technical difficulty of raising the roads over six feet was realized. This is due to the numerous intersecting roads, driveways, and parking areas that could not be constructed without extreme

grades. The existing beachfront roads in Hancock and Jackson have a typical grade elevation of 5.0 and the general grade elevation for US 90 in Harrison County is 10.0 although it varies from elevation7.0 to 16.0 depending on the exact location. With the existing road elevations, a top elevation of 11.0 was selected for study in Hancock and Jackson County and a top elevation of 16.0 was selected for study in Harrison County for a total of three options. It was also recognized that LOD-3 would require that a barrier be placed at the mouths of the bays to be effective against back-flooding. The location of the barriers are shown in Section 2-1 of the Engineering Appendix.

Some areas of the coast were not associated with beaches or existing roadways that allowed for a continuous defense line. When including environmental and/or technical reasons, these areas could only be viewed as stand-alone projects such as ring levees. These areas included five communities in Jackson County and two in Hancock County. For discussion purposes, these were also included in LOD-3. Each of the conceptual ring levees have been evaluated for construction at two elevations, 20.0 and 30.0 (except for the Forest Heights neighborhood) . The costs also included interior drainage, pumping stations, gates for roadways and overtopping protection. Some sites also have one or more alternate alignments. The alternate alignments were selected to lessen the impacts on wetlands, lessen the intensity of wave action or to decrease the construction costs versus adding non-structural solution areas. With all ring levee elevations and alternate alignments, there are 24 different options for further consideration.

Further inland, an existing railroad grade provided a levee-like barrier to storm surge from Katrina in some areas. This railway extends all the way across the State crossing both St. Louis Bay and Biloxi Bay. In Harrison County, the railway parallels the coastline just a few blocks inland. Using a parallel, high-ground alignment as the railway system, an inland barrier was envisioned that could be constructed to such an elevation as to protect from a large storm surge, even larger than Katrina. Like LOD-3, this system would require that the bays be closed off with barriers from surge to be effective. As LOD-4, this barrier was studied at elevations up to the maximum storm surge or maximum possible intensity (MPI) storm that could be predicted based on simulated hurricane events. These selected elevations are 20.0, 30.0 and 40.0. Possible options for LOD-4 also included omitting the surge barrier across St. Louis Bay. This would require that LOD-4 be terminated along the east side of the bay. An alternate alignment to satisfy this option was selected at Menge Avenue in Pass Christian where the LOD-4 levee could be extended northward to higher ground. This option would also leave the town of Bay St. Louis without any type of surge protection. If this alternate alignment is used, Bay St. Louis hurricane defenses could be included as a ring levee with an option under LOD-3. Many alignments for project termination on the western and eastern sides of the state were considered before one that was selected, mostly due to technical and environmental reasons. This system would not cross the Pearl River on the western side of the state nor the Pascagoula River in Jackson County. Including all the different elevations and alignments for LOD-4, there are a total of 22 options including the six options for the surge gates. A general discussion of the LOD's is included in Section 2.1 of the Engineering Appendix. A more detailed discussion can be found in Part 3 of the Engineering Appendix.

As high-level protection from the largest storm surge event, the limits of surge predicted from the MPI event was transposed to maps. While actually a non-structural measure, it was designated as LOD-5. It would be an area north of any potential surge damage that would be recommended for location of critical infrastructure such as hospitals, long-term care facilities, and emergency facilities.

To proceed with initial cost estimates, various components of the structural options were conceptually designed to the selected elevations described in previous paragraphs. The initial elevations selected for each component of the lines of defense are assumed to bracket a wide range of potential storms with corresponding surge elevations. Using these preliminary designs, rough order of magnitude cost estimates were completed for each of the structural options. These cost estimates can used to develop cost curves for future use to estimate rough estimates after final

design elevations are selected. With these cost curves, future studies can also select varied levels of protection based on risk assessments as well as taking into account future estimates of relative sea level rise.

8.2 Evaluation of Measures – Formulation Round Two

Evaluation of measures carried forward into Round Two focused on the discussion about modeling results and technical analyses on each measure and site or problem area. The study team then discussed their evaluations as a group to arrive at consensus as to what was being discovered about the benefits or issues with each remaining measure, and its conceptual application to the site or problem area in question. This evaluation process also involved the application of numerous technical models, to determine, for instance, the behavior of waves, under both a without-project and with-project condition, or the benefit over time to a particular ecosystem created by a particular measure.

At the same time as the lines of defense were being modeled and evaluated, it was also realized that some measures would not provide damage reduction from large storms. As an example, a dune placed on the beach could only be constructed to a height far short of what would be required to prevent surge resulting from a large storm event. It was also evident that several areas of the coast could not be included in continuous line of defense and would have to be addressed with either a ring levee system, or a non-structural solution. An example of this would be the original concept of a series of state-wide barriers along the coast following any one of several alignments (LODs). One concept that was initially discussed was a hard seawall type barrier southward (seaward) of any development across the entire coast, but later modified to follow only existing beach-front roadways. This eliminated the technical and environmental problems of crossing sparsely populated marshes and blocking extensive river systems. Locally populated areas were included, but defended with barriers not included with the continuous lines. These areas were included in the LOD system with individual ring levees.

From the planning session of five conceptual lines of defense, resulted numerous refined variations of each of the lines. The evaluation of these concepts was made in a study team meeting that included engineers, environmentalists, planners, and geologists. Information from along the coastline was utilized that included large scale aerial photography, topographic maps, navigation maps, and a large collection of pre and post-Katrina photographs.

The list of measures developed for each problem area was refined once more, and additional data presented for consideration, based on their continued technical, environmental, and cost-effectiveness feasibility, based on more detailed input from the resource agencies, public and private entities, and technical staff, with consideration of their ability to be combined into multi-purpose alternatives, capable of dealing with more than one identified problem at a given site. The screened list of measures was then combined into a group of well-balanced alternatives, that included both non-structural and if applicable, structural measures that could potentially address the entire suite of environmental problems plaguing an individual site or problem area. Formulation of these alternatives also incorporated the following criteria:

- Does a potential alternative provide for an improvement in function and/or habitat values of significant resources that might also provide for potential preservation of fish and wildlife and their habitats?
- Does a proposed action or project negatively impact low income or minority populations and/or children [i.e. Executive Orders (EOs) Environmental Justice and Protection of Children)?
- Does a proposed alternative provide a potential reduction in coastal erosion?

- Does a proposed alternative provide a potential reduction in the extent or level of saltwater intrusion (encroachment)?
- Does the proposed project fit in, with, or complement the objectives of the State of Mississippi and/or locals' plans and desires for the area?
- Does the proposal contribute to the short-term or long-term recovery of coastal Mississippi?

Using these questions, as continued evaluative tools, the PDT provided for consideration, the additional criteria:

- effectiveness;
- completeness;
- acceptability; and,
- efficiency (cost-effectiveness).

Additional evaluative questions being asked by the study team, in its development of information on potential measures, but not considered screening criteria, also included:

- Does that measure provide a reduction in risk at that specific site, or in other locations?
- Does that measure provide a reduction in damage at that specific site, or in other locations?
- Can that measure be combined as a component of a multi-purpose alternative?
- Can that measure be capable of dealing with more than one identified problem at a given site?
- Does a proposed measure or alternative provide an increase in the level of education on hurricane risks?
- Does a proposed measure or alternative provide a decrease in time before one would be warned of an impending hurricane event (i.e., more time to prepare)?
- Does a proposed measure or alternative provide an increased level of precision in information on the level of threat (i.e., better information on landfall location and magnitude of the event)?
- Does a proposed measure or alternative provide an increase in the effectiveness of hurricane/storm warning to area residents and visitors?
- Does a proposed measure or alternative provide better education as to evacuation options, required items a family or business might want to evacuate, and definitive information on routes to safety?
- Does this effort duplicate or compliment the work of others?
- Does the problem (or would lack of a solution to the problem) enhance protection of life?
- Does the problem (or would lack of a solution to the problem) enhance protection of property?
- Is a potential alternative sustainable after implementation?
- Does a potential alternative still provide a potential reduction in hurricane or storm damage (if applicable)?
- Does a potential alternative still provide a potential reduction in coastal erosion (if applicable)?
- Does a potential alternative still provide a potential reduction in the extent or level of saltwater intrusion (if applicable)?

- Does a potential alternative still provide for potential preservation of fish and wildlife and their habitats (if applicable)?
- Does a proposed action or project negatively impact low income or minority populations?
- Is the cost reasonable in the light of the risk and consequences of not implementing the project?
- Are there unresolved issues (with other groups or organizations) regarding this problem or proposed solution that may lead to longer implementation times?
- Would a proposed activity or project have potential regulatory and/or environmental issues that would preclude being implemented in the near-term?
- Does the proposed project fit in with, or complement the objectives of the State and/or locals plans and desires for this area?
- Would the implantation of the proposed project preclude other future options that may have a higher level of contribution or damage reduction?
- Does the proposed project contribute to the short, or longer-term recovery of coastal Mississippi?

8.3 Comparison of Measures – Formulation Round Two

Comparison of Round Two measures consisted of presentation of conditions and potential change in conditions, under "No-Action", future "without-project", and future "with-project" conditions for each site or problem area. Data presented for comparison in Round Two included preliminary costs, benefits (monetary, or economic, environmental outputs, societal, etc.) to be derived from measure implementation, problems related to implementation, more detailed design considerations, environmental outputs and potential impacts, potential damages prevented, geotechnical/site considerations, more detailed technical requirements, source material and source area considerations, variations in materials that could be used to solve the problem in a similar way, species benefits or impacts considerations, and many other technical, environmental, or economic issues.

Comparison of damage reduction measures centered on the performance of a given measure in regards to how effectively it reduced surge height and extent, compared to other measures of similar output. This involved numerous iterations of potential height and geographic coverage, since literally thousands of potential alignments of levee or embankment might be created. The goal in damage reduction measure formulation was to reduce damages to the maximum extent possible for a given type of structural or non-structural measure. While many different measures such as levees, gates, seawalls, relocations, or structure elevations might produce a similar monetary damage reduction benefit, numerous iterations were necessary to develop the best measure of a given type, given the large number of variations that might be required to produce the least costly and most productive measure. The most notable differences in flood damage reduction measures were found when comparing 3rd line of defense (elevated seawall and beach roadways) with nonstructural measures along the same area (see Table 26). The structural measures are very costly for the amount of damages reduced compared to the nonstructural measures, especially when taken in consideration that they must be constructed in tandem with surge barriers across the bays.

Table 26.
Expected Annual Damage Reduction

Measures	Expected Annual Damage Reduction (Annual $)[1]	Residual Damage (Annual $)[1]	Implementation Cost ($)	Annual O&M (Annual $)	Average Annual Cost (Annual $)
(No Action)	$0	$0	$0	$0	$0
Seawall/Elevated Roadway[2]	$52,030,000	$374,010,000	$5,002,500,000	$60,148,000	$306,127,051
ABFE Nonstructural at Seawall/Elevated Roadway Footprint	$200,860,000	$225,180,000	$8,483,400,000	$110,000	$417,249,166

1/ Expected annual damages reduced are rounded to the nearest thousand dollars.
2/ The elimination of the seawall and elevated roadway option also eliminates the beach and dune placement options that are dependent on the raising of the seawall and roadway.

Comparison of ecosystem restoration measures involved the comparison of costs versus outputs, expressed in functional capacity units, FHIs, and other measures of benefit output, such as achievement of a critical level of restoration in regards to the number of a certain plant required to sustain long-term restoration of a specific ecosystem, or removal of an invasive plant that would prevent full restoration of that ecosystem.

The following four models were once again utilized by the MsCIP environmental team to evaluate the performance comparison of potential ecosystem restoration measures:

- Mississippi and Alabama Gulf Coast Tidal Fringe HGM;
- Wet Pine Savannah HGM;
- FHI Coastal Maritime Forest/Beach-Dune Evaluation Model; and
- GIS-based Wetland Restoration SDSS.

Future with-project conditions were established by the study team, in analysis of the specific functions that would be modified, either positively or negatively, at each site. Those scores are presented in the Environmental Appendix, and summarized below.

Table 27.

Summary of Environmental Benefits.

Site	Restoration Acres	Plan	Average Annual Functional Unit Benefit
Turkey Creek	879	Existing Condition (plans 1-2)	0
Turkey Creek	689	Existing Condition (plans 3-4)	0
Turkey Creek	190	Existing Condition (plans 5-6)	0
Turkey Creek	879	No-action plan (plans 1-2)	0
Turkey Creek	689	No-action plan (plans 3-4)	0
Turkey Creek	190	No-action plan (plans 5-6)	0
Turkey Creek	879	plan 1	2,046

Site	Restoration Acres	Plan	Average Annual Functional Unit Benefit
Turkey Creek	879	plan 2	1,352
Turkey Creek	689	plan 3	1,565
Turkey Creek	689	plan 4	815
Turkey Creek	190	plan 5	481

Franklin Creek	56	plan 4	150

(1) AAFU's are based on a 50-year period of analysis.

(2) See Economic Appendix for cost-effective analysis.

8.4 Screening of Measures – Formulation Round Two

Screening of remaining measures again involved comparison of the relative benefits, impacts, costs, societal impacts, or other outputs of a given plan, as compared to each other and the "No-Action" Plan. Screening of measures during Round Two also included the incorporation of data presented to the public and other local decision-makers, as part of the public involvement process.

Screening in Phase Two eliminated a large number of site-specific measures, such as certain seawall or beach berm/dune alternatives, based on their failure to achieve significant damage reduction. Screening also eliminated a large number of embankment/levee options, as simply too environmentally damaging or technically infeasible for further consideration. These included levees,

embankments, and floodwalls across embayments and channels in western Hancock and eastern Jackson Counties, levees across Grand Bay Marsh, or the Pearl River delta systems, and across wetland areas along other parts of the coast, as shown in Table 28.

Table 28.

Summary of Round2 Measures Screened

Measures Screened During Round 2
Increasing Islands Footprint (Option A)
Hancock 40' Dune @ Elevated Roadway (Option A)
Hancock 50' Dune @ Elevated Roadway (Option B)
Hancock 20' Dune @ Elevated Roadway (Option C)
Hancock 30' Dune @ Elevated Roadway (Option D)
Hancock Dune Option A plus sea oats (Option E)
Hancock Dune Option B plus sea oats (Option F)
Hancock Dune Option C plus sea oats (Option G)
Hancock Dune Option D plus sea oats (Option H)
Hancock 55' Dune and beach berm (Option I)
Hancock Dune Option I plus sea oats (Option J)
Harrison 40' Dune @ Elevatied Roadway (Option A)
Harrison 50' Dune @ Elevated Roadway (Option B)
Harrison 20' Dune @ Elevated Roadway (Option C)
Harrison 30' Dune @ Elevated Roadway (Option D)
Harrison Dune Option A plus sea oats (Option E)
Harrison Dune Option B plus sea oats (Option F)
Harrison Option C plus sea oats (Option G)
Harrison Dune Option D plus sea oats (Option H)
Harrison 55' Dune and beach berm (Option I)
Harrison Dune Option I plus sea oats (Option J)
Hancock Seawall/Elevated Roadway at Elevation 11
Harrison Seawall/Elevated Roadway at Elevation 16
Jackson Seawall/Elevated Roadway at Elevation 11
Biloxi Bay Surge Gate at Elevation 20
St Louis Bay Surge Gate at Elevation 20

The screening of measures also included the dropping of large-scale modifications (i.e., adding additional height, closing off the channels between them) to the barrier islands or Mississippi Sound, as not creating a significant (or even moderate) reduction in damages and being too environmentally destructive. In addition, measures, such as offshore breakwaters and other offshore features designed for damage reduction, were also dropped from further consideration due to their inability to significantly affect surge height or extent.

The Corps' SDSS tool further allowed the team, in cooperation with the USFWS and MDMR, to further screen those potential wetland restoration areas that were forwarded from earlier phases of study. A subset of potential restoration sites were identified by use of SDSS then ground-truthed by the MsCIP environmental team, including ERDC, Corps, MDMR, and USFWS, for verification of

appropriate properties, the degree of environmental damage, and to further refine the applied No-Action and With-Project functional scores for each area and each potential alternative output.

This effort was also further coordinated at this stage with the ongoing efforts of the MsCIP non-structural damage reduction committee, and their results were used as the team identified potential restorations sites in coastal Mississippi that had been previously developed residential or commercial sites that no longer hosted significant amounts of development and were, therefore, subject to analysis as both buy-out and restoration sites. Thirty-four restoration sites were selected for further analysis based on this screening process, based on a combination of results from the SDSS tool and input from MDMR and USFWS personnel using personal local knowledge of the study area and adjacency to existing sensitive protected natural areas (i.e. State and/or Federal lands). In addition, eleven sites that also appeared as State of Mississippi Initiative Projects were additionally evaluated for inclusion as part of the next round of evaluations by the MsCIP study team.

9 FORMULATION ROUND THREE

The final refinement of measures consisted of incorporating comments from team members and stakeholders, as well as making adjustments based on the last set of evaluations, to narrow the list down to a small set of alternatives to be analyzed at the highest level of detail. This final refinement was directed at maximum effort to identify the most cost-effective options within the four key areas of study:

- Ecosystem restoration for preservation of fish, wildlife and habitat functions and values;
- Saltwater intrusion/encroachment reduction;
- Hurricane Storm Damage Reduction;
- Coastal Erosion Reduction.

Each was refined to achieve better benefits, more damage reduction, more ecosystem benefit, greater freshwater inflow or better salinity reduction, particularly during the period of greatest importance in the life cycles of select organisms.

9.1 Refinement of Damage Reduction Measures in the Lines of Defense Framework

Based on the screening of measures in Formulation Round Two, many of the options presented in the Engineering Appendix were dropped from further consideration. After the evaluation of the many measures, the screening process has reduced the ones that will be either recommended for construction, accelerated engineering and design, or further study. In some cases, the measures being carried forward are alternates of options that were initially proposed, but modified to accommodate enhanced damage reduction, environmental reasons or technical problems. As presented in the Engineering Appendix, the following discussions are listed by order in the defined "Lines of Defense" (LOD).

Modifications to the Mississippi barrier islands were identified as LOD-1. The islands were among the first storm reduction aspects that were discussed in Mississippi's Recovery Plan. Calls to restore the islands to a pre-Camille condition presented an option that encompassed work on all four islands, but was met with resistance from the National Park Service who has ownership of the vast majority of the islands. Through many meetings with the Park Service, a selection of options were formulated that could be combined into an alternative that would meet the objectives of Mississippi's

plan plus win the endorsement of the Park Service. This alternative also meets three of the four key areas defined above. The alternative selected for accelerated engineering and design consists of the restoration of Ship Island, littoral zone sand additions at the east ends of Petit Bois and East Ship Island, changes in maintenance dredging practices that meet the requirements of the Regional Sediment Management Practice, and a study to define the best restoration option for Cat Island. With the consideration that the Park Service has an immediate need to mitigate storm damage to two historical sites on the islands, an emergency project has also been included to help protect these sites until the full comprehensive project is completed. Without support of the NPS, the other options were screened out from further consideration.

Measures that would provide some degree of protection along the mainland beaches (LOD-2) initially included constructing dunes in several configurations, some with planted dune vegetation and other without, and elevating adjoining roadways (LOD-3). Having either of these measures at sufficient elevation to avoid requiring non-structural storm damage elements in areas landward was found to be technically difficult without major modifications to the immediate coastline. The results of the surge modeling has indicated that unless the top elevation of the dune or roadway is comparable to a levee with certification, the property owners behind the structures would still be required to elevate or relocate as if these structures were not in place. Due to the technical problems and associated non-structural requirements, most of these options were screened from further consideration. The remaining option associated with the beaches and adjoining roadways is the addition a low dune with dune vegetation onto the existing beaches due to environmental benefits.

Many parts of the Mississippi coast do not have the topography or population density that would support the concept of a continuous barrier such as a levee parallel to the coast. To help provide some storm defense for these areas, ring levees could be used. The alignment of these ring levees was initially selected to provide the maximum protection for the population centers. As these alignments were evaluated, alternate alignments were selected in some cases to minimize impact on wetlands, provide attenuation from direct wave attack, or decrease the quantity of fill required fro levee construction. Examples of this can be found in the alternate alignments at Gulf Park Estates, Belle Fontaine, and Pascagoula in Jackson County. The crest elevations for these ring levees could vary depending on the amount of risk that that community wanted to assume. The recommended crest elevation is typically designed for a surge and waves with a 0.2 percent annual chance of being exceeded.

As a set of options that could provide an inland defense from larger storms (LOD-4), a conceptual design has been completed that would be comprised of inland levees with surge barriers across the mouths of the two large bays in Mississippi. In combination, this barrier could extend from the first watershed divide east of the Pearl River in Hancock County westward to the last watershed divide west of the Pascagoula River following parallel to an existing railway. This barrier could be designed to provide a defense from a very large storm, but would have some aspects that may not have public or political support. Depending on the selected crest elevation, the levee may be hardly noticeable in some areas with naturally high topography such as portions of Biloxi, but may be a very high feature in areas with low topography such as Pass Christian. Another feature is the surge gates that would be required to prevent back-flooding into the bays. Evaluation of the requirements to have the gates as a component revealed that the closure of St. Louis Bay could be omitted provided that the levee did not cross into Hancock County, but the closure of Biloxi Bay is required to provide any beneficial defense for Gulfport or Biloxi. The surge gate evaluation provided an alternate levee alignment in Harrison County that could omit this defense in western Harrison County and Hancock County. The alternate alignment would parallel the railway through Harrison County westward to the Menge Avenue crossing where the levee would turn north to high ground. Due to its east-west extent in Harrison County, this portion of the levee system could also be used to support the construction of a major roadway on top of the levee by widening the crest.

Due to the accelerated nature of this study, the study team was unable to develop a sufficient level of detail for any of the structural measures to recommend for construction. Further, based on input received at the various public and stakeholder meetings, the structural measures did not receive a majority of support. Therefore, the study team feels that should decision makers like to see any of the structural measures further developed, a full feasibility study would be required. There is, however, sufficient information to make basic comparisons with nonstructural flood damage reduction measures.

9.2 High Hazard Area Risk Reduction Plan

While the nonstructural measures were also emotionally charged at public meetings, there was consensus that buyouts as a result of the 2005 storms be limited as to not displace large portions of communities. This resulted in a two-pronged approach to homeowner's assistance. The first stage involves the buyout of those properties that have been frequently flooded, or are at very high risk of future damage due to storm surge. The second is to develop a strategy where buyouts in large contiguous areas along the coast can occur shortly after the next devastating storm event. The significant portion of the population feels that they may be too far along with the rebuilding process to start all over in another location at this time. Further information on the High Hazard Area Risk Reduction Plan can be found in the Nonstructural Appendix.

9.3 Elevating Structures and Relocating Municipal Services

In addition to the High Hazard Area Risk Reduction Plan, the team developed alternatives for pilot projects involving new methodologies in elevating structures in the hardest hit areas of Waveland, Mississippi, and relocating municipal services to higher ground in Moss Point, Mississippi, as shown in Figure 16. . Further information on these pilot projects can be found in the Nonstructural Appendix.

Figure 16: Moss Point Public Facilities Relocation Pilot Project

9.3.1 Maximum Possible Intensity Line

The one option that will provide a very low degree of risk from storm surge is in moving all future critical or emergency infrastructure construction northward of the extent of the surge based on the "Maximum Possible Intensity" (MPI) storm event modeling. While this is only a recommendation without a program requirement, it has no direct cost.

9.4 Refinement of Ecosystem Restoration Measures

The environmental PDT was faced with assessing the three counties in coastal Mississippi, which consists of hundreds of thousands of acres of uplands, wetlands, urban, coastal forest, etc. This assessment had to be conducted in a consolidated amount of time in order to meet the MsCIP condensed schedule; therefore, the team quickly began compiling various data, such as topographic maps, navigational charts, water quality reports, soil maps, etc, that would be useful in assessing potential restoration efforts. The environmental PDT also had ERDC develop the GIS-based SDSS analysis tool that could effectively assist the team in quickly narrowing down restoration sites.

The plan formulation process began with defining the overall comprehensive natural system and its current state post-hurricane season of 2005. The MsCIP environmental PDT compared the post-hurricane conditions to the pre-hurricane conditions. In some cases, environmental contrasts were very great while in other instances not much change had occurred. The environmental team worked with a variety of Federal, state, and local entities to adequately address the magnitude of problems plaguing coastal Mississippi. Minor problems to complex integrated problems were identified and discussed amongst the team members – structural, environmental, and non-structural.

Development of a comprehensive list of problem areas consisted of single or multiple problems associated with a given site that were first identified as having been caused or exacerbated by the 2005 hurricane events. These sites were identified with damage to fish and wildlife resources, and/or saltwater intrusion. The following measures were carried forward.

9.4.1 Freshwater Diversion

A freshwater diversion project may serve to enhance the wildlife resources of the area. While there is some disagreement to the benefits of freshwater diversion projects (Turner 2006), further study will assist in determining if such diversions are ecologically feasible in eastern Jackson County, Grand Bay Savannahs and Marshes, and in western Hancock County, Hancock County Marshes. Freshwater diversions enable redistribution of freshwater and much needed sediments to these systems that are experiencing losses and erosion. Hydrodynamic circulation, salinity, and water quality model calibrations have been conducted for Mississippi Sound. Existing or baseline salinity and water quality distributions were established for March – September 1997 and 1998. Alternative freshwater diversion scenarios were developed and simulated with the calibrated models to examine changes to the baseline salinity and water quality distributions. Freshwater diversion did impact the environment in Jackson and Hancock Counties. Oysters are sensitive to specific ranges of salinity; therefore, freshwater diversions have the potential to either enhance or threaten the resource.

Several projects are presently being considered to divert freshwater from the Mississippi River or other sources as a mechanism to promote reversing a historic increase in salinity in the Mississippi Sound/Biloxi marshes area in order to support fresher marshes and oyster reef health and productivity; thus, enhancing both their economic value and the ecological services they provide.

Oysters not only support a commercial fishery but interact directly with local hydrodynamic conditions, affecting currents, flow conditions, and sedimentation patterns (Lenihan 1999). They filter large amounts of phytoplankton and detritus exerting a powerful influence on water quality, phytoplankton productivity, and nutrient cycling of estuaries (Dame 1996). Oyster reefs provide habitat for a wide range of other invertebrates present either on the oyster shell itself or in the interstices between shells. Oyster reefs also support numerous resident, transient, and juvenile fish and decapod species and may provide a refuge from predation and poor water quality conditions.

Oysters are sensitive to specific ranges of salinity; therefore, freshwater diversions have the potential to either enhance or threaten the resource. For instance, where the average salinity exceeds 15 ppt oysters often experience increased predation rates by oyster drills whereas young oysters are more susceptible to certain diseases at salinities greater than 9 ppt (Cake 1983; Chatry et al. 1983). Similarly, salinities averaging below 7.5 ppt can inhibit oyster growth and sexual maturation while salinities that persist for extended periods of time below 2 ppt can result in direct mortality (Sellers and Stanley 1984). The relationship between oyster productivity and river flow is a complex one and there does not appear to be a close link between oyster harvests and freshwater inflow (Turner 2006).

Alternately, the water diverted from riverine sources not only has lower salinity, but it usually carries more sediment and nutrients. Diversions may result in areas of excess nutrients and thus cause algal blooms, lower light attenuation and other signs of eutrophication. Therefore, any proposed diversion project needs to be carefully evaluated in order to insure the maximum probability that proper habitat and water quality conditions are met. Because of the potentially large number of projects that might require evaluation, it is essential that a screening tool be developed to cost-effectively identify those proposals which warrant the level of detailed study required to make informed decisions. It is essential that proposals that have no likelihood of success are eliminated early in the evaluation process in order to maximize the effectiveness, eliminated negative impacts from poorly designed projects, and reduce costs of evaluating the remaining candidates.

In an effort to initiate the proper evaluation of freshwater diversions, a water quality model, which is based on the CE-QUAL-ICM water quality model code, is coupled to output from a three-dimensional hydrodynamic model of the region, which is based on the CH3D hydrodynamic model (Dorth et al 2007). The version of CH3D with sigma coordinate in the vertical dimension is being used. The model grid extends seaward beyond the Chandeleur Island and includes Mobile Bay, Lake Borge, Lake Pontchartrain, the Inner Harbor Navigation Channel of New Orleans and the Mississippi river Gulf Outlet Channel. Predicted water quality constituents, including nutrients, phytoplankton, dissolved oxygen, temperature, salinity, and underwater light intensity, were evaluated for several scenarios and compared to modeled existing baseline conditions to assess relative changes.

The water quality model was applied for three alternative scenarios: (1) diversion of freshwater flow from the Mississippi River at Bonnet Carre' spillway, (2) diversion of freshwater flow from the Mississippi River at Violet Marsh, and (3) diversion of all of the Escatawpa River flow into Grand Bay. The Bonnet Carre' diversion varied by month while the Violet Marsh diversion was a constant flow of 7,500 cubic feet per second. The Escatawpa diversion is the flow that occurred in the Escatawpa River during 1998, and those values were varied daily in the model. The water quality model was applied for the period April through September 1998 using the same inputs as the final calibration run except for different hydrodynamics and different boundary conditions for the diverted flow and associated concentrations of the flow. The hydrologic model was run with the same conditions as used for the base conditions used in the water quality model calibrations for 1998 except that the additional freshwater flows were introduced.

In an effort to apply this water quality data to ecological issues, MsCIP and ERDC convened a panel of representatives from TNC, MDMR, and USM at the Gulf Coast Research Laboratory. The aim of the panel is to suggest simplistic ecological models that can be incorporated with projections from the combined hydrodynamic and water quality models to identify simulations which might result in an improvement in oyster habitat quality. The panel has identified several key attributes that need to be incorporated into the evaluation of freshwater diversion options. The first is that salinities average as closely as possible to the optimal range for oyster health and productivity. This is clearly of critical importance since the primary purpose for contemplating freshwater diversions is to improve habitat conditions for oysters. Second, a diversion should not result in extended periods of low salinity resulting in mortality or poor growth and reproduction. This consideration is particularly critical during times of high river flow or other extreme conditions. Third, a diversion should not unduly influence habitat conditions for other critical resources. Diversions that result in favorable conditions for oyster health may not be conducive to other equally important resources. For instance, most seagrasses do poorly at salinities less than 20 ppt. A diversion that results in excellent conditions over the prime commercial beds but drives salinities below 20 ppt in the seagrass elsewhere would not be acceptable. Other important habitat requirements that should also be considered for seagrass health include light availability and nutrient concentrations. These environmental concerns associated with water diversions, in addition to potential impacts on important fisheries species of those areas, require conservative actions and more study of potential impacts (positive and negative) of such practices for the long-term sustainability of nearshore and estuarine resources.

As an example, the results from a simulated diversion of 7,500 cubic feet per second of Mississippi River water near Violet, Louisiana are presented in Figure 17. The results suggest that 180 days after initiation of the diversion salinities were lowered in western Mississippi Sound. Dortch et al. (2007) sufficiently warrant additional examination. However, at present, absolute salinity values predicted by the model poorly match calibration data. Further refinement of the models should correct this limitation and must be made to allow the usefulness of the model results for estimating potential beneficial or deleterious effects on oysters and other coastal resources.

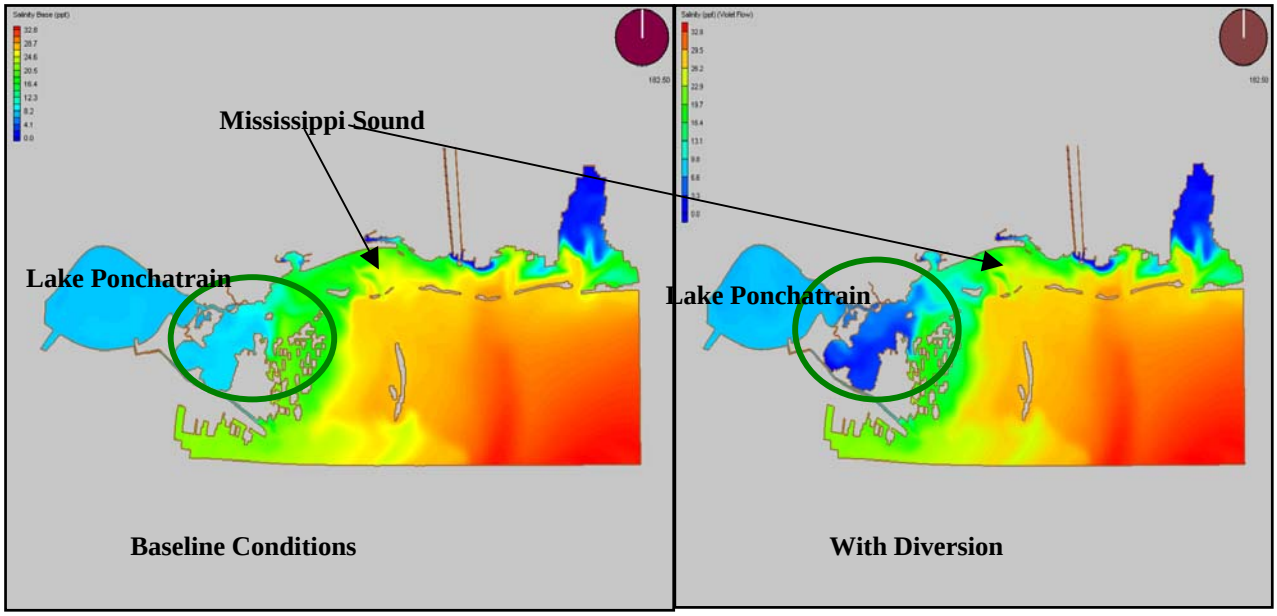

Figure 17. Projected Salinity Values 180 days after initiation of a diversion of 7,500 cfs of Mississippi River water at Violet, LA Simulated Diversion of Mississippi River into Lake Borgne Near Violet, Louisiana

Results also showed that diversion through the Bonnet Carre and through the Escatawpa/Grand Bay system have the potential to significantly influence coastal salinities. The more freshwater (i.e. 0 to about 20 ppt) areas are designated with blue and green colors while more saline (i.e. 20 to 33 ppt) conditions are designated with yellow, orange and red colors.

Ongoing and future studies can be used to refine the hydrodynamic and water quality model and tighten the calibrations. This will allow for better integrating the water quality results to ecological concepts. Also, this preliminary effort just developed information for some possible discharge scenarios in order to do a sensitivity analysis as to whether diversion could potentially affect the areas of concern. These efforts showed the potential for freshening the systems. Future studies and model runs will need to be performed to test precise operational discharge plans and seasonal influences.

Historically, the estuarine marsh within the Grand Bay NERR represented the former deltaic environments of the Pascagoula and Escatawpa Rivers in eastern Jackson County. The outlets of these rivers have shifted westward over time, severely limiting the inflow of freshwater, nutrients, and sediments into the Bayou Cumbust area of the reserve.

Currently, it is speculated that much of the freshwater entering the Grand Bay NERR estuary is from surface runoff through Bayou Heron and Bayou Heron, within the Bangs Lake Hydraulic Unit, measuring approximately 21,374 acres. Human disturbances to the area have also altered historic sheet flow and surface water flows into the area, as well as the natural migration of the Pascagoula and Escatawpa Rivers. A freshwater diversion project in the area, if feasible, may serve to enhance the wildlife resources of the area. The need for freshwater diversion at the Grand Bay savannahs and marshes would help restore the predominant wet pine savannah habitat. Shoreline erosion along the Grand Bay area (i.e. loss of the Grand Batture Islands) has also contributed to the increased salinity in the area.

The proposed project will seek to develop a refined hydrodynamic model for the area, inputting biological, water quality, and physical data into the model to evaluate a variety of freshwater

diversion scenarios. This work represents a critical first step in the final assessment of potential water diversion projects for this area. Community information will be solicited and a public workshop will be held to share the results.

Diversion of Mississippi River freshwater and/or sediments in the vicinity of Violet, Louisiana has been strongly considered because of a number of positive factors. These include proximity of the river to target coastal wetlands restoration areas, strong public support, and high confidence in potential environmental benefits. The Violet Diversion Project is under consideration by the MsCIP (Corps, Mobile District) and Corps, New Orleans District as a freshwater diversion project that could potentially have a positive impact to the Hancock County Marshes. Preliminary results from modeling a simulated diversion of 7,500 cubic feet per second of Mississippi River water near Violet, Louisiana, suggest that after 180 days of initiation of the diversion, salinities were lowered in Western Mississippi Sound sufficiently to warrant additional examination (Dortch et al 2007). Further refinement of the models should address current limitations and must be made to estimate potential beneficial or deleterious effects on oysters, seagrasses, marsh systems, and other coastal resources. Although the idea is viable, at this point, additional information is needed to determine current problems within Hancock County Marshes and potential impacts to existing coastal resources as well as navigational impacts.

9.4.2 Environmental Restoration of Historical Wetland Sites

The Corps, Mobile District began investigations for identifying potential environmental restoration sites for the purposes of storm and flood damage reduction, flood reduction, preservation of fish and wildlife habitat, and removal of habitable structures within high hazard areas. When residential and/or commercial structures and/or land are purchased for the purpose of restoring floodplain areas (i.e. non-structural component), the structures are demolished and the land is no longer available for residential and/or commercial development. Historically, when land is purchased across the U.S., it is left with all or some of the infrastructure at the site rather than restoring it to its historic setting. With the MsCIP environmental plan, land that is purchased (i.e. non-structural component – refer to Non-structural Appendix) would then be restored into historical functional wetlands. The Corps, Mobile District, in cooperation with ERDC, developed a tool to help identify potential restoration sites throughout the study area.

Development of a GIS based SDSS tool allowed the Corps, Mobile District, working in cooperation with the USFWS and MDMR, to identify and prioritize potential wetland restoration areas throughout coastal Mississippi (Lin 2007). A detailed discussion of this GIS based SDSS tool is included in the Environmental Appendix. A subset of potential restoration sites were identified by the SDSS tool and then ground-truthed by the MsCIP environmental team, including ERDC, Corps, MDMR, and USFWS. This interagency team allowed us to both confirm the accuracy of the SDSS results and to collect additional on-site information pertinent to restoration efforts. There are some major benefits in using a GIS-based SDSS approach to wetland restoration. First, it allows for the relatively rapid assessment of the large number of restoration sites across the wide study area. Second, potential sites can be evaluated and restored in a watershed or landscape context, which allows us to comprehensively evaluate the overall natural system. This approach can maximize the benefits of wetland restoration, as opposed to simply restoring wetlands where convenient or where property is available. Essentially use of this SDSS tool allowed the MsCIP environmental team to assess the entire coastline as a holistic natural system; thus, the team was more effectively able to analyze needs in coastal Mississippi.

The SDSS effort resulted in the following products:

1) A ModelBuilder based SDSS tool, which can be subsequently edited and applied to other areas along coastal Mississippi in the future as funding becomes available;

2) Maps, such as aerial photography, topographic, soil layers, etc., depicting areas in the study region that have a high probability of being successfully restored into wetland functions that buffer and/or store stormwater, and provide suitable habitat for fish and wildlife;

3) Photograph documentation and data sheets containing information on ground-truthed potential restoration sites.

This project has been further coordinated with the ongoing efforts of the MsCIP non-structural flood-proofing committee, and their results were used as the team identified potential restorations sites in coastal Mississippi. The selection of 34 restoration sites, discussed in detail in Section *4.1.5.2 Environmental Restoration of Historical Wetland Sites* of the Environmental Appendix, was based on a combination of results from the SDSS tool and input from MDMR personnel based on local knowledge of the study area and adjacency to existing sensitive protected natural areas (i.e. State and/or Federal lands).

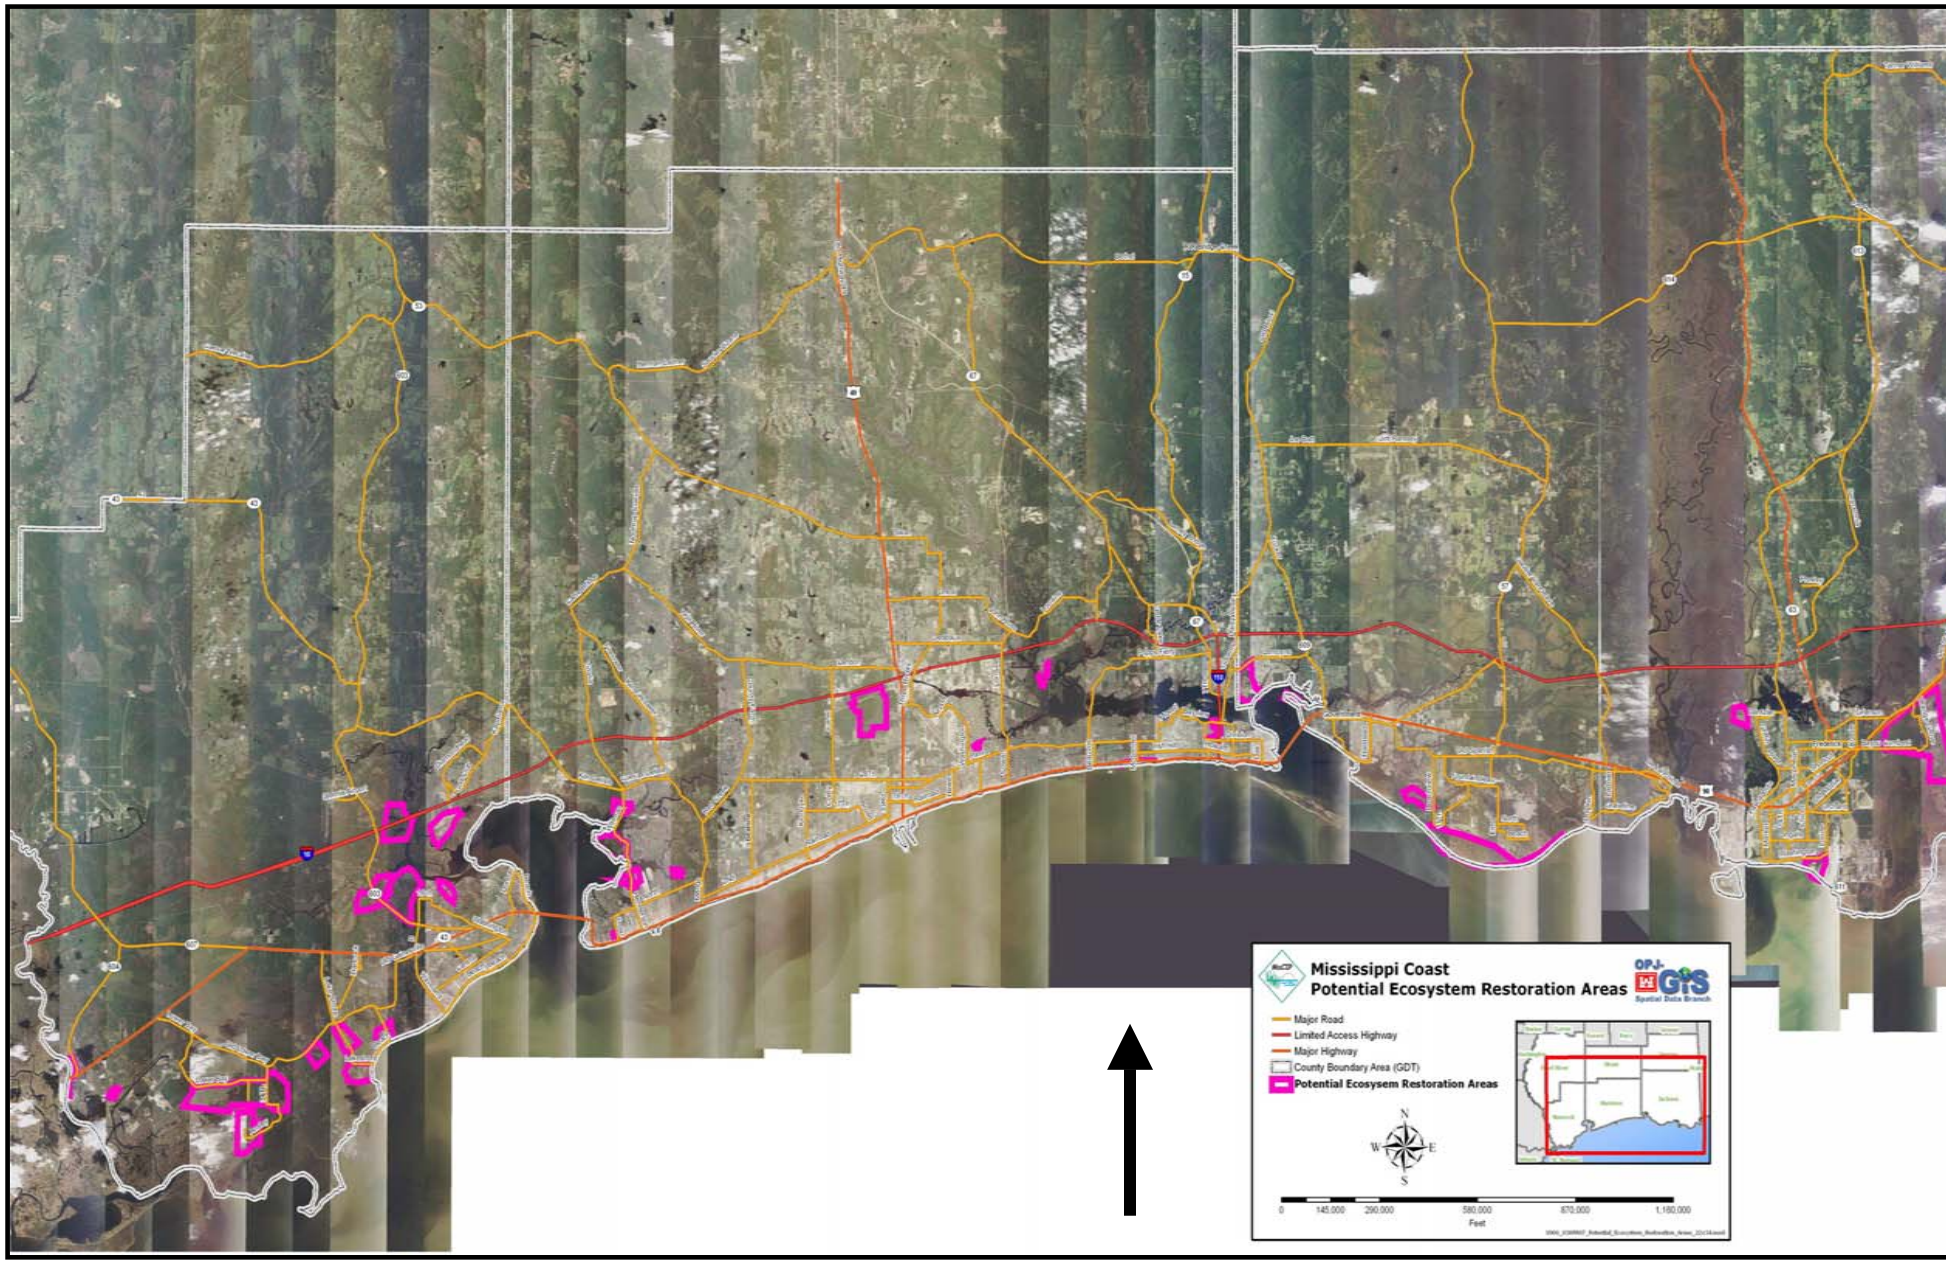
The SDSS tool evaluated potential wetland restoration sites that had been initially selected based on having a non-natural land cover (i.e. urban, deforested, and agricultural land cover, based on MDMR 2001 land cover GIS layer) and were located in the 100-year floodplain (Lin 2007). Numerous potential environmental restorations sites were initially identified. This initial group of sites was narrowed down based on the results of the SDSS. Sites with the following characteristics were screened out:

- < 5 acres in size
- Restorability class of Low or Medium Low
- Habitat class of Low or Medium Low
- Storm Surge/Flood Protection class of Low

Initial screening yielded hundreds of sites that were then reviewed by the Corps, Mobile District, MDMR, and USFWS personnel. A more detailed discussion of the initial sites yielded is located in the Environmental Appendix. Following detailed assessment, the Environmental PDT screened these sites and selected the following 34 final restoration sites. These final environmental restoration sites include a combination of those identified based on the SDSS results, as well as some additional sites. These were made using only the non-natural land-use and 100-year flood calculations as the original site selectors (i.e. no damage layers were used), and sites were greater than or equal to 5 acres (Table 29).

Table 29.

Environmental Restoration Sites in Coastal Mississippi



Site	Restoration Acres	Environmental Setting
(1) Pearlington, Hancock	76 acres (State owns 2,200 acres in the Pearlington area)	Emergent aquatic vegetation Bayhead Swamps trees Bayhead Swamps shrubs Riverine/levee forests
(2) Pearlington South, Hancock	11 acres	Emergent aquatic vegetation Bayhead Swamps trees Bayhead Swamps shrubs Riverine/levee forests
(3) Port /West, Hancock	49 acres	Emergent aquatic vegetation
(4) Ansley, Hancock	2,023 acres (State owns 6,000 acres west of Lakeshore Road)	Emergent aquatic vegetation Wet pine savannah
(7) Lakeshore, Hancock	275 acres	Emergent aquatic vegetation

Site	Restoration Acres	Environmental Setting
(8) Bayou Caddy/Lakeshore, Hancock	362 acres	Emergent aquatic vegetation
(9) Clermont Harbor, Hancock	209 acres	Emergent aquatic vegetation
(10) Bayou La Croix, Hancock	259 acres	Emergent aquatic vegetation
(11) Shoreline Park, Hancock	889 acres	Emergent aquatic vegetation
(12) Chapman Road, Hancock	146 acres	Emergent aquatic vegetation
(13) Jourdan River – Interstate 10 Development, Hancock	638 acres	Emergent aquatic vegetation
(14) Diamondhead, Hancock	433 acres	Emergent aquatic vegetation
(15) Delisle, Harrison	120 acres (State owns 1,000 acres)	Emergent aquatic vegetation Bayhead swamps trees Bayhead Swamps shrubs
(16) Ellis Property, Harrison	443 acres	Emergent aquatic vegetation Pine savannah - wet pine flatwoods.
(17) Pine Point East, Harrison	103 acres (State owns 40-50 tax forfeited lots)	Emergent aquatic vegetation Wet pine savannah habitat
(18) Pine Point West, Harrison	83 acres (State owns 40-50 tax forfeited lots)	Emergent aquatic vegetation Wet pine savannah habitat
(19) Pass Christian Beach Front, Harrison	21 acres	Emergent aquatic vegetation Bayhead swamps trees Bayhead Swamps shrubs
(20) Pass Christian Site – Bayou Portage, Harrison	43 acres	Emergent aquatic vegetation Bayhead swamps trees Bayhead Swamps shrubs
(21) Brickyard Bayou, Harrison	14 acres	Emergent aquatic vegetation Bayhead swamps trees Bayhead swamps shrubs
(22) Biloxi River – Shorecrest, Harrison	15 acres	Emergent aquatic vegetation Bayhead swamps trees Bayhead swamps shrubs Riverine/levee forests
(23) Biloxi River – Eagle Point, Harrison	17 acres	Emergent aquatic vegetation Bayhead swamps trees Bayhead swamps shrubs Riverine/levee forests
(24) Biloxi Front Beach - South of Highway 90, Harrison	40 acres	Dune System
(25) Keegan Bayou, Harrison	54 acres	Emergent aquatic vegetation Wet Pine Savannah habitat
(26) St. Martin, Jackson	467 acres	Emergent aquatic vegetation
(27) Fort Point, Jackson	83 acres	Emergent aquatic vegetation
(28) Pine Island, Jackson	237 acres	Emergent aquatic vegetation
(29) Belle Fontaine, Jackson	1,516 acres	Dune System
(30) Griffin Point, Jackson	182 acres	Emergent aquatic vegetation
(31) Bayou Chico, Jackson	258 acres	Emergent aquatic vegetation
(32) Grand Bay/Bayou Cumbest, Jackson	2,666 acres	Emergent aquatic vegetation
(33) Wachovia, Hancock	1,200 acres total – 800 marsh, 200 forested, 200 savannah	Emergent aquatic vegetation, Bayhead Swamps trees Bayhead Swamps shrubs Riverine/levee forests
(34) Ansley, Hancock	900 acres – 800 marsh, 100 forested	Emergent aquatic vegetation, Wet pine savannah

Site	Restoration Acres	Environmental Setting
(35) LaFrancis Camp Trenaisse, Hancock	45 acres total – all open water	Open Water
(36) DuPont, Harrison	650 acres – 170 marsh, 480 forested	Emergent aquatic vegetation, Bayhead Swamps trees Bayhead Swamps shrubs Riverine/levee forests
(37) Danztler, Jackson (Alternate)	900 acres – 500 marsh, 385 forested	Emergent aquatic vegetation, Bayhead Swamps trees Bayhead Swamps shrubs Riverine/levee forests
(38) Pascagoula River Marsh, Jackson	11,150 acres	Emergent aquatic vegetation, Bayhead Swamps trees Bayhead Swamps shrubs Riverine/levee forests

This project has been further coordinated with the ongoing efforts of the MsCIP non-structural flood-proofing committee, and their results were used as the team identified potential restorations sites in coastal Mississippi. The following selection of 38 restoration sites was based on a combination of results from the SDSS tool and input from MDMR personnel based on local knowledge of the study area and adjacency to existing sensitive protected natural areas (i.e. State and/or Federal lands). See Figure 18 for the specific identified environmental restoration sites.

Figure 18 Potential Ecosystem Restoration Site

9.4.3 Submerged Aquatic Vegetation

The continued survival and growth of seagrasses (i.e. SAVs) may be threatened by the cumulative effects of man's activities, in addition to, natural processes in the coastal marine environment. Natural causes of SAV (i.e. *D. wrightii, C. manatorum, T. testudinum*, and *R. maritime*) decline, such as disease, storm events, salinity fluctuation, and hypoxic events, coupled with declining water quality caused by anthropogenic eutrophication currently threaten the health of many SAV systems (Montague and Ley 1993, Durako and Kuss 1994, Olesen and Sand-Jensen 1994, Zieman et al 1994). These habitats provide vital refuges, feeding, resting, staging, and spawning grounds for a variety of species found in Mississippi Sound and also in the Gulf of Mexico. Past studies throughout the years have attributed anywhere from 50% to 90% of all marine species to utilize this vital habitat at some point in their life state.

In 1969, an estimated 20,000 acres of SAVs were documented and as of 1998, only 2000 acres were documented (Moncrieff 1998), see Table 30. Dramatic decreases have been noted on every Mississippi barrier island. Areas of SAV habitat loss coincide with areas where rapid coastal erosion and massive long-term movement of sand has been well-documented (Otvos 1981 and Oivanki 1994). Loss of vegetated areas corresponds with potential loss in water clarity over time due either to: (1) anthropogenic influences, (2) cyclic shifts in precipitation patterns, which would affect both salinity and turbidity, or (3) a combination of these factors (Moncrieff 1998). Primary reasons for the disappearance of SAVs are most likely an overall decline in water quality, extended periods of depressed salinities, and physical disturbances, such as tropical storms and hurricanes (Moncrieff 1998). Physical loss of habitat and decreased light availability coupled with declining water quality are the most visible features that directly affect SAVs (Moncrieff 1998). Moncrieff (1998) identified approximately 14,900 acres as being suitable SAV habitat [i.e. Potential Seagrass Habitat (PSGH)].

Table 30.

SAV Historical, 1992 and Potential Habitat

Location	1969 (acres)	1992 (acres)	PSGH
Buccaneer State Park	206	55	316
Cat Island	598	169	5,128
Ship Island	1,536	253	1,603
Dog Keys Pass	2,079	0	1,149
Horn Island	5,567	530	4,350
Petit Bois Island	1,690	364	1,810
Point-aux-Chenes Bay	1,306	627	534
Totals	12,982	1,998	14,890

Reference: Moncrieff 1998

Areas of SAV habitat loss coincide with areas where rapid coastal erosion and massive long-term movement of sand has been well-documented (Otvos 1981 and Oivanki 1994). Loss of vegetated areas corresponds with potential loss in water clarity over time due either to: (1) anthropogenic influences, (2) cyclic shifts in precipitation patterns, which would affect both salinity and turbidity, or (3) a combination of these factors (Moncrieff 1998). Primary reasons for the disappearance of SAVs are most likely an overall decline in water quality, extended periods of depressed salinities, and physical disturbances, such as tropical storms and hurricanes (Moncrieff 1998). Physical loss of habitat and decreased light availability coupled with declining water quality are the most visible features that directly affect SAVs (Moncrieff 1998). Moncrieff (1998) identified approximately 14,900 acres as being suitable SAV habitat (i.e. PSGH).

Mapping techniques have very much advanced since Moncrieff's last mapping of Mississippi Sound in the late 1990s. In discussing a potential SAV restoration project with the scientific community, the one consistent need was to re-inventory the existing SAVs in Mississippi Sound. Mississippi Sound and barrier island sedimentary processes as related to seagrass biomes are important, but not currently available. The nature, extent and volumes of sediment types within both Mississippi Sound and the barrier islands are constantly in flux, necessitating a comprehensive and ongoing assessment of sedimentary dynamics. Further studies would determine existing conditions and remaining problems that challenge establishment of SAVs within Mississippi Sound. Opportunities exist to create partnerships with other Federal and state resource agencies, and NGOs to begin identifying potential SAV restoration and establishment projects. Restoration efforts should target historical locations as a starting point to begin determining current conditions and challenges, including water quality issues, available nursery stock of plants, etc., prior to implementation of actual projects.

9.4.4 Deer Island Ecosystem Restoration

Deer Island, located within the boundaries of Harrison County, Mississippi near the mouth of Biloxi Bay and the City of Biloxi, has a history of tropical storm damage. Damages from these storms has varied based on varying degrees of storm surge, wave action and wind depending on the speed, intensity, direction of travel, and proximity of the given storm. Figure 19 displays a recent aerial photograph of Deer Island, which damage was acerbated during Hurricane Katrina .

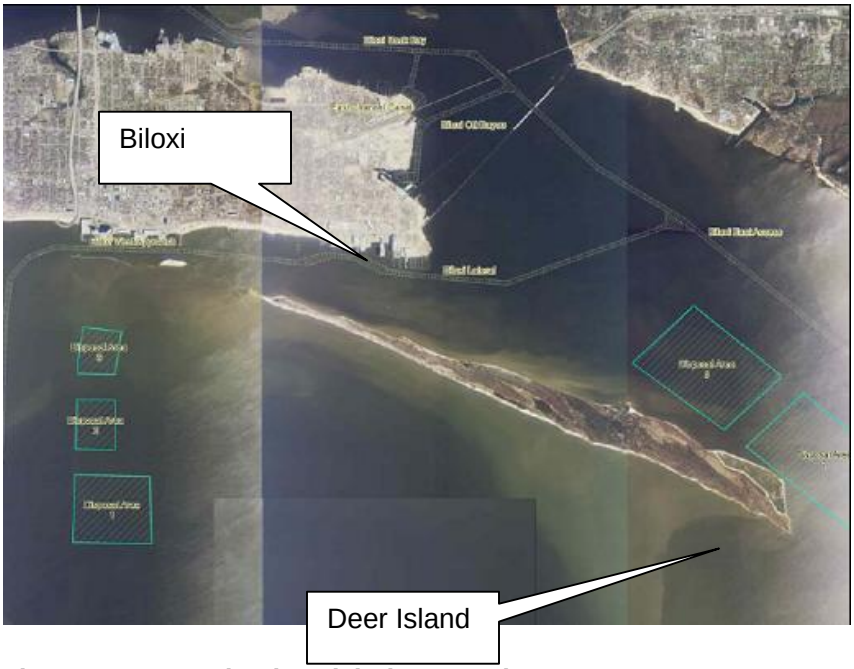


Figure 19 Deer Island Aerial Photograph

The island is considered a mainland remnant and is not part of the coastal barrier system of islands along the Mississippi Coast. The island contains a diversity of habitat areas including beach/dune areas, marsh area, and maritime forest areas. It's proximity to the City of Biloxi provides a certain amount of protection to the city from waves generated by approaching hurricanes. This protection comes at a cost to the island as that energy affects the seaward shoreline and the interior marshes. It has been estimated that the island has lost approximately 300 acres or about 34 percent of its area since 1850, due to eroding shoreline.

In 2003, because of loss of wetland marsh areas, an aquatic restoration project was proposed near the eastern tip of Deer Island. The project was authorized under the continuing authority of Section 204 of the Water Resources Development Act of 1992, as amended. Dredged material from maintenance of Biloxi Harbor was used to create approximately 45 acres of tidal marsh on the north shore of the east end of the island. Wetland vegetation was planted by over 100 volunteers in April 2005. The created marsh area withstood Hurricane Katrina with minor scouring within the site but with a minor breach of the containment dike of the marsh area. Plants within the marsh area are thriving. Figure 20 displays the existing Section 204 project.

Figure 20. Existing Section 204 Project

Currently, the island has a large breach on its western end and a small breach has formed in the central area of the island in what is know as the Grand Bayou area. As the island degrades, the Federally authorized shallow draft Biloxi West Approach and Biloxi Lateral navigation channels that run between the City of Biloxi and Deer Island will experience increased shoaling and will require more frequent, and costly, maintenance dredging activities. Dredging frequency in this area is typically as much as half the frequency of similar nearby channels. Deer Island also provides erosion protection to the mainland of the City of Biloxi. As the island continues to degrade, the impacts of increased wave action on the mainland shoreline will increase the amount of storm damages that can be suffered by commercial development congregated in this area. Figure 21 displays the general location of the west end breach and the Grand Bayou area.

In summary, there is a need to restore the shoreline of Deer Island, fill the breach areas, repair/improve existing marsh and maritime forest areas, and add additional marsh area. These

efforts will provide protection to the mainland areas behind the island and improve critical coastal wetlands.

Figure 21. Areas of Concern

There are a number of possible solutions that can be implemented to provide improvements on Deer Island. Restoration of the seaward shoreline is needed with filled areas graded and planted to establish/restore marshes and maritime forest areas. Restoration of the created marsh at the eastern end of Deer Island is needed to preserve, maintain, and enhance the aquatic habitat established by that project. Listed below, in order of precedence, are the proposed actions and their approximate cost:

Because of the shoreline losses and concern about the breaches and the resulting loss of area, following Hurricane Katrina, Federal authorization and funds were provided to restore the lost seaward shoreline and fill the breaches. That project, scheduled to begin construction in early 2008, will provide for ecosystem restoration as well as preservation of critical coastal wetlands by restoring portions of the island and its shoreline lost during storm events. However, funding for this effort is not adequate to completely restore the entire seaward shoreline. The estimated cost to completely restore the seaward shoreline of Deer Island is about $4,750,000.

Repair/replace the damaged portion of the containment dike: The small failure area of the containment dike during Hurricane Katrina contributed to the loss of material within the site. Repair or replacement of this portion of the containment dike is necessary to restore the marsh area to its

pre-Katrina level and would prevent further loss of marsh area. The estimated cost to repair/replace this portion of the containment dike is about $200,000.

Add/replace material in the containment area: New material is needed to restore the marsh area to its pre-Katrina level. This additional material will replace that which has been lost and will also be used to raise marsh areas that had through consolidation had become too low to sustain marsh habitat. The estimated cost to add this material is estimated to be about $600,000.

Analyze new stone training dikes on the north and south ends of the island: Initially, short training dikes were constructed on the eastern side of the Section 204 project. These dikes were to protect the containment dikes from erosive forces within the Mississippi Sound. Review of the failure of the containment dike suggests that the shortness of the training dikes may have contributed to the failure. A modeling analysis of the training dikes needs to be conducted to insure that the dikes are long enough to prevent future failures. The estimated cost to conduct this analysis is about $50,000.

Lengthen stone containment dikes on north and south ends: Lengthening the stone containment dikes may be necessary to reduce/eliminate the reoccurrence of failure of the containment dike. The modeling noted above will help in this determination. The estimated cost to lengthen the stone containment dikes is about $1,000,000.

Create additional marsh area adjacent to existing created marsh: The existing created marsh area and that which will be restored with the shoreline restoration project help to replace marsh areas that have been lost over time on Deer Island. The creation of additional marsh area will help to offset losses that have occurred and will enhance aquatic habitat on the island. The existing created marsh successfully demonstrates the durability of the design of the marsh area as well as the selection of the site for the creation of the marsh. The project proved its ability to withstand a fairly strong hurricane event during Hurricane Katrina. An additional marsh area can be created adjacent to the west side of the existing created marsh. The created marsh area will be about 20 acres in size and is estimated to cost about $2,400,000.

The total estimated cost for the proposed work items totals $9,000,000. Figure 22 displays the location of the proposed work items 2 through 6.

Figure 22. Location of Proposed Work Items

9.5 Evaluation of Measures – Formulation Round Three

Evaluation of measures carried forward into Round Three focused on the results of the final refinement of modeling results and technical analyses on each final measure or alternative. The study team then discussed their final evaluations as a group, to arrive at consensus as to what alternatives would be compared in the System of Accounts analysis. This final evaluation process involved the determination of final surge and wave heights for a given event frequency, surge behavior under these same events, costs required for those structural and non-structural designs or lists of features applying to a certain design level, final determination of damage reduction benefits derived for a certain design, potential societal and other OSE benefits and outcomes fort each plan, or the benefit over time to a particular ecosystem created by a particular measure. Table 31 shows the results of the final evaluation of measures to be carried over into the System of Accounts analysis.

Measure	Tidal Habitat Restored (Acres)	Tidal Habitat Lost (Acres)	Non-Tidal Habitat Restored (Acres)	Non-Tidal Habitat Lost (Acres)	Damages Reduced / Avoided ($)	Residual Damages ($)	Cost to Implement Plan ($)	Local Cost Burdens (1-10)	Regional Economic Benefits (1-10)	Cultural and Historical Heritage (1-10)	Public Service Disruptions (1-10)	Personal Impacts (1-10)	Long-Term Sustainability (1-10)	Consequences of Plan Failing (1-10)	Residual Risk (1-10)

Table 31 Evaluation Results of Final Plans

9.6 Comparison of Measures – Formulation Round Three

Comparison of Round Three measures consisted of presentation of conditions and potential change in conditions, under "No-Action", future "without-project", and future "with-project" conditions for each site or problem area, in both a descriptive presentation, and also in a "System of Accounts" comparison format. Data presented for comparison in Round Three included revised costs, benefits (monetary, or economic, environmental outputs, societal, etc.) to be derived from measure implementation, potential impacts related to implementation, detailed design considerations, environmental outputs, damages prevented, geotechnical/site considerations, more detailed technical requirements, source material and source area considerations, and other technical, environmental, or economic issues. The "System of Accounts" analysis presents information in four separate "accounts" or categories for comparison, that include "National Economic Development" (NED), which in this case only compares and contrasts the cost-effectiveness of each group of alternatives, "Regional Economic Development "(RED), which discusses the potential regional impacts of each group of alternatives, Environmental Quality (EQ), which discusses potential positive and negative environmental impacts of each group of alternatives and their environmental quality implications, and Other Social Effects (OSE) evaluations, which discusses and contrasts the potential social, and other effects of each group of alternatives.

The alternatives were also compared and contrasted according to their achievement of the additional criteria of a) effectiveness; b) completeness; c) acceptability, and d) efficiency (cost-effectiveness) according to applicable Corps guidelines.

In addition to these four traditional accounts, information on potential risks, uncertainties, and consequences, is also presented in System of Accounts format, for comparison at the same level of scrutiny of the information presented in other accounts.

After the weighting of the metrics, a multi-criteria decision analysis was made to obtain a multi-attribute utility, or stakeholder risk score for each of the final plans. This number rates each alternative as a percentage of a theoretical "perfect plan" (in the eyes of the stakeholder groups). In other words, the higher the percentage, the more acceptable the alternative should be to that stakeholder group.

The stakeholder risk scores presented in the system of accounts help to identify plans that meet stakeholder expectations. The results of the metric weighting analysis identified four distinct stakeholder groups, each clearly showing which accounts are more important to them. Therefore, the "perfect plan" would show high scores from each of the cluster groups, as well as rate well in the other accounts. Table 32 summarizes how the stakeholder risk scores vary for each alternative by each cluster group.

The full set of system of accounts evaluation tables are presented in the Main Report. A detailed discussion of the development of stakeholder risk scores, including an example systems of account evaluation table is presented in the Risk Appendix.

10 SELECTION OF RECOMMENDED MEASURES, PLANS AND ACTIVITIES

Members of the public, agencies, and local decision-makers, weighed in on the final list of alternative plans. Those plans identified by the “best-buy” analysis as possessing Federal interest in implementation, and passing all screening criteria, fell into one of these categories:

a) Inclusion as a project recommended for Construction Authorization;
b) Inclusion as a project requiring additional preconstruction engineering design (PED) for specific features (i.e. a long-term solution that needs more technical analyses based on the complexity of the system);
c) Inclusion as project(s) under a Programmatic Plan Authorization;
d) Inclusion as a project requiring additional Feasibility Studies Authorization (i.e. requiring extensive evaluation); and
e) Inclusion as a project requiring Advanced Design Studies for Innovative Concepts Authorization.

10.1 Projects Recommended for Construction Authorization

Eight (8) potential restoration sites (Barrier Islands, Deer Island, Turkey Creek, Bayou Cumbest, Franklin Creek, Admiral Island, Dantzler, and Bayou Cumbest SAV), and two flood damage reduction areas (Forrest Heights and HARP), were chosen as initial projects to be carried forward in the environmental component of the MsCIP Comprehensive Plan and Integrated Programmatic EIS. The potential restoration sites are located throughout the study area, in each coastal county. Two of the sites consist of restoring emergent tidal marsh habitat, three other sites restore wet pine savannah habitat, and one restores SAVs in Bayou Cumbest, one will restore the barrier islands, and one will complete restoration efforts on Deer Island. These sites allow the Corps, Mobile District to demonstrate the planning process involved in developing environmental restoration measures at each site and county, development of alternatives, and selection of a cost-effective restoration plan for each potential environmental restoration site. If authorized for further study, all other potential ecosystem restoration sites previously identified in this report would go through a similar planning and evaluation process under a Programmatic Authority.

In addition, two pilot projects are tentatively recommended. The Moss Point Municipal Structure Relocation Project is a pilot project involving relocating municipal services to higher ground within Moss Point. The information gained from this effort could help other communities in relocating their facilities to reduce the risk from future storm surge. The Waveland Flood Proofing Project is a pilot project involving new methods for elevating structures in the hardest hit areas of Waveland. The information gained from this effort could help other communities in elevating structures using FEMA's new 550 guidelines, thereby reducing their risk from future storm surge. These projects are discussed in more detail below, and are fully developed in the Non-structural Appendix.

10.1.1 Turkey Creek Ecosystem Restoration

This project site is located in north Gulfport, Mississippi, adjacent to U.S. Highway 49, a major north-west thoroughfare, and within the impaired Turkey Creek watershed. The area is becoming increasingly urbanized and development pressures are resulting in increased wetland degradation and loss by direct filling with the incumbent decrease in flood storage capability. The Turkey Creek site is approximately 880 acres of predominately undeveloped land. The site is divided by an east-west running railroad berm and contains a number of dirt road/paths and several miles of drainage ditches. These drainage ditches were constructed in the past in an effort to drain the site and control the drainage across the site into specified areas in hopes of making the site more attractive for development. Approximately 689 acres are south of the existing railway and 190 acres are located north. The railway berm effectively separates the two portions of the site and therefore these areas functions separately. The site is primarily comprised of degraded pine savannah wetland habitat. The elevated railway berm, miles of drainage ditches, and undeveloped fragments the wetland habitat and substantially alters the hydrology of the wetlands located to the north. Hurricane Katrina damages and/or destroyed much of the remaining habitat (wind and salt damage to vegetation as well as salinity increases in the soils from the surge) such that the area has been determined to be incapable of unassisted recovery.

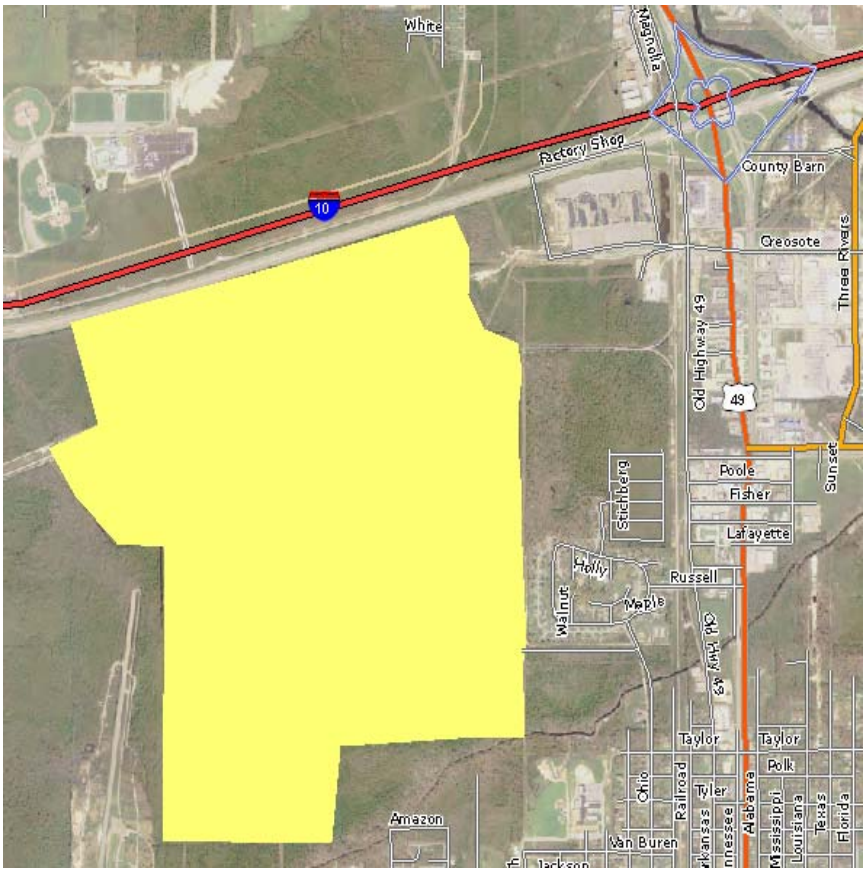

Figure 23. Location of Turkey Creek Restoration area.

Several plans were evaluated in order to determine the most cost-effective plan for restoration. The Turkey Creek site had an HGM assessment performed in 2000, using the *Regional Guidebook for Applying the Hydrogeomorphic Approach to Assessing Wetland Functions of Wet Pine Flats on Mineral Soils in the Atlantic and Gulf Coastal Plains* (Rheinhardt et al 2002). Results from this earlier assessment were used to establish baseline (current) conditions at the site.

The east-west railroad berm effectively divides the site into two distinctive areas for restoration options. These options included evaluating on the basis of addressing the degraded nature of the entire site (879 acres), the northern portion of the site (190 acres), and the southern portion of the site (689 acres). Any restoration option considered would require the acquisition of the specific portion of the site as well as any removal and/or demolition of structures.

Seven plans were developed (including no action) that considered filling in man-made ditches, maintaining native vegetation (by either burning or mowing), and excavating and removing the existing roadbeds and any additional fill placed by man. The economically ineffective plans were identified and eliminated in a cost-effective analysis which can be found in the Economic Appendix. An economically ineffective plan is a plan that costs more or the same as a subsequent plan but produces less benefit than that subsequent plan. Of the seven plans analyzed, three plans were eliminated because they produced less benefit at greater cost than a subsequent plan as shown in Figure 24. All three of the plans eliminated included the use of mowing as a management measure for restoring and/maintaining the wet pine savannah habitat.

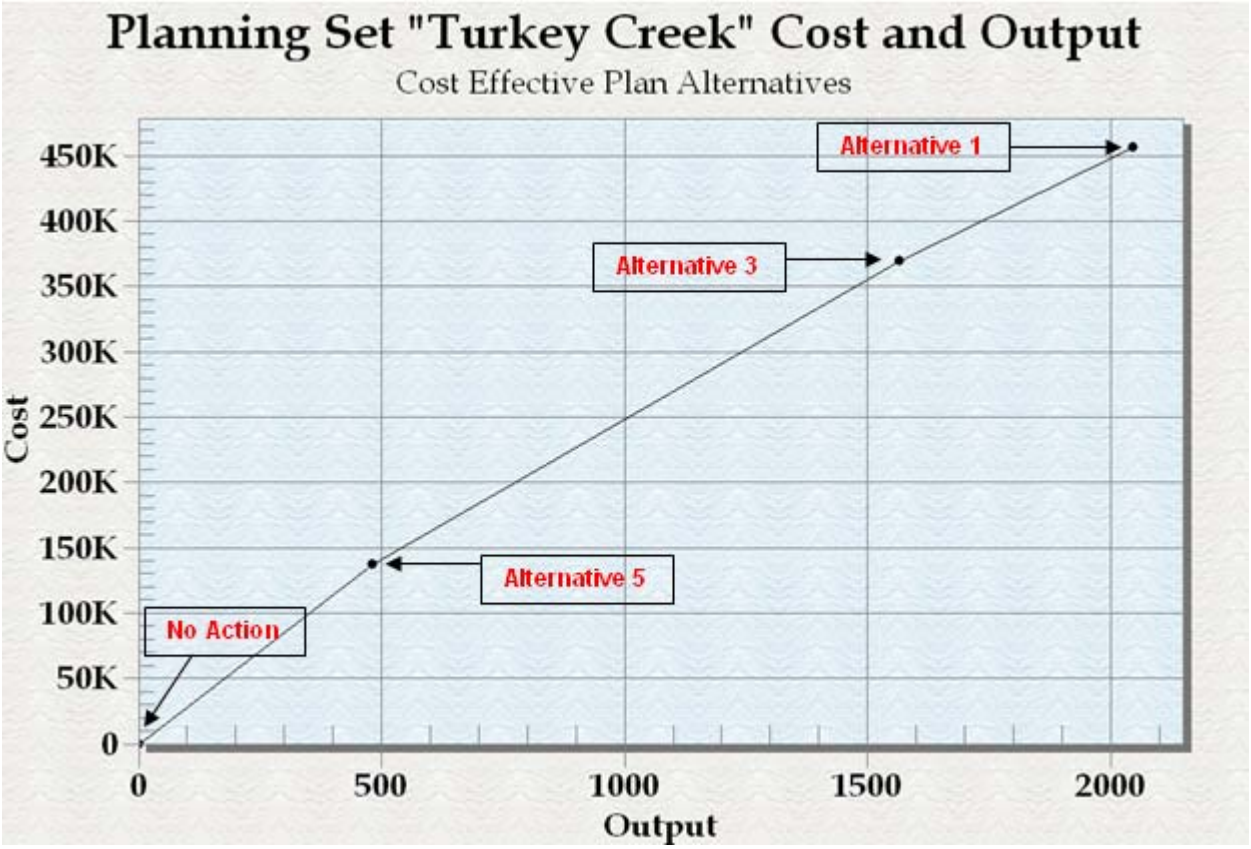

Figure 24. Display of Cost Effective Alternatives for the Turkey Creek Area

Of the three remaining plans, Plan 3 (shown as Alternative 3 above) proved to be the most cost-effective. There is not very much difference in the benefits gained in Plan 1 when compared to extra cost. There is, however, a much bigger difference in benefits for a small amount of cost when comparing Plan 3 with Plan 5, or the No Action Plan.

As shown in the System of Accounts (Table 1.18-3), the major differences between the 4 remaining plans are with the sustainability of the plan, as well as the cost to maintain the site. Again, Plan 3 has a distinct advantage over the larger Plan 1 because of the sheer volume with regards to maintenance, and in sustainability because of getting water to flow through the railroad barrier.

An essential component necessary when selecting the recommended plan at Turkey Creek was the need for burning. Burning allows the wet pine savannah environment to continue naturally as a functioning system. Although mowing does effectively keep understory plants from over colonizing the area, it does not simulate the natural conditions (i.e. seed germination, heating the pine bark, etc.) Therefore, Plan 2 is not as effective as Plans 1 and 3 due to its mowing component. The benefits are also different between Plans 1 and 3, primarily due the acreages. Plan 1 includes both the north and south parcels while Plan 3 included only the south parcel. Also, the man-made barrier within the project site will make it more difficult to maintain the necessary hydrology (water flow) for Plan 1. The MsCIP team took all of these factors into consideration and believes that Plan 3 would do the best job of achieving the desired environmental restoration outputs (i.e. a functioning wet pine savannah) while also being a cost-effective plan.

Plan 3 consists of requires the acquisition of 689 acres of predominately undeveloped land, filling the previously constructed draining ditches, excavating and removing existing roadbeds and any

additional fill, and maintaining vegetation growth by burning the project area in the initial year of construction as well as maintaining it by burning every three years over the life of the project as needed. The acquisition of properties and the demolition of structures will cost $762,000. The restoration work on the site will cost approximately $ 5,108,000, and the average annual cost of operating and maintaining the project is estimated to be $47,000.

10.1.2 Bayou Cumbest Ecosystem Restoration

The Bayou Cumbest site is located in the extreme southeastern portion of Jackson County adjacent to Bayou Cumbest and the Mississippi Sound. The area contains approximately 373 acres to be restored to emergent tidal marsh. The area currently consists of a degraded tidal marsh, as well as filled and developed areas (see Figure 25). Due to the severity of Hurricane Katrina, most of the residential development was severely damaged or destroyed. The area contains low elevations and since most residential structures have been destroyed, the opportunity exists reduce the risk of future hurricane and storm damage and to restore the once existent tidal marsh. Pursing this initial restoration project would relocate residents outside of the low-lying areas and would help demonstrate the environmental recovery of this area of the valuable marsh resource. In addition, this would also provide additional future storm surge protection to the overall coastal area by increasing the natural protection that marsh provides.

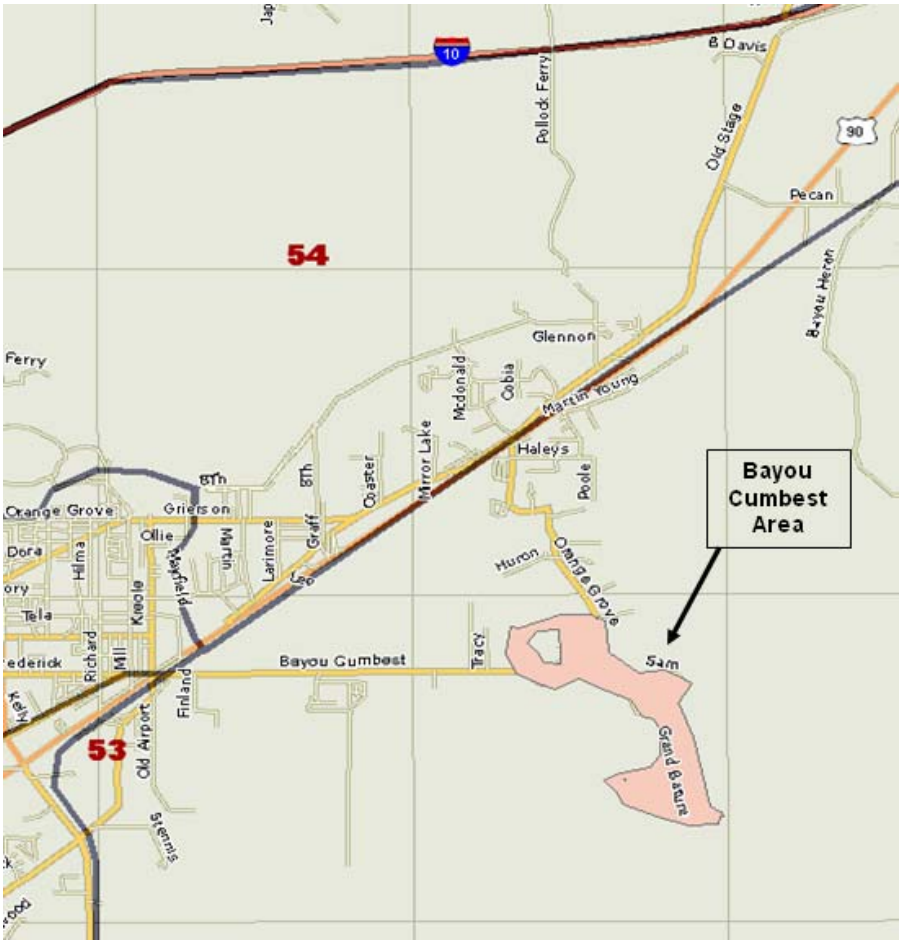

Figure 25 Bayou Cumbest Area

The acquisition of 178 parcels and the removal of 62 structures would be required for all alternatives considered for this area. The acquisition of many, if not, all of the parcels with structures for this area are being considered as part of a Jackson County request to the Mississippi Emergency Management Agency for funding via FEMA Hazard Mitigation Grams Program (HMGP). As part of all of the plans (except the no action plan) considered for this site, the Corps in cooperation with the State and Jackson County would undertake the acquisition of those properties not acquired via the HMGP which would effectively reduce the future risk of damage from hurricane and storm surges. No Ecosystem Restoration would be performed as part of the HMGP, and the 373 acre area would be allowed to remain in a degraded nature, as with the No Action alternative. Alternatives to this option include the implementation of various management measures including excavating old fill material, removing exotic species, filling in existing artificial ditches, and planting native vegetation at various densities ranging from a ½ meter to 2 meter spacing.

These management measures were combined to create seven plans (including no action) that were analyzed to determine the cost-effectiveness of each. The economically ineffective plans were identified and eliminated to determine which plans are cost-effective. An economically ineffective plan is a plan that cost more or the same as a subsequent plan but produces less benefit than that subsequent plan. Of the seven plans analyzed, Plans 4 and 5 were eliminated because they produced less benefit at greater cost than a subsequent plan. These plans lack the aspect associated with filling the artificial ditches and with native vegetation at 0.5 and 1.0 meter spacings. Similarly, Plan 6 was eliminated because it would not be a “best-buy” plan in that it produces much less benefit for only slightly less cost than Plan 3 as shown in Figure 26 below.

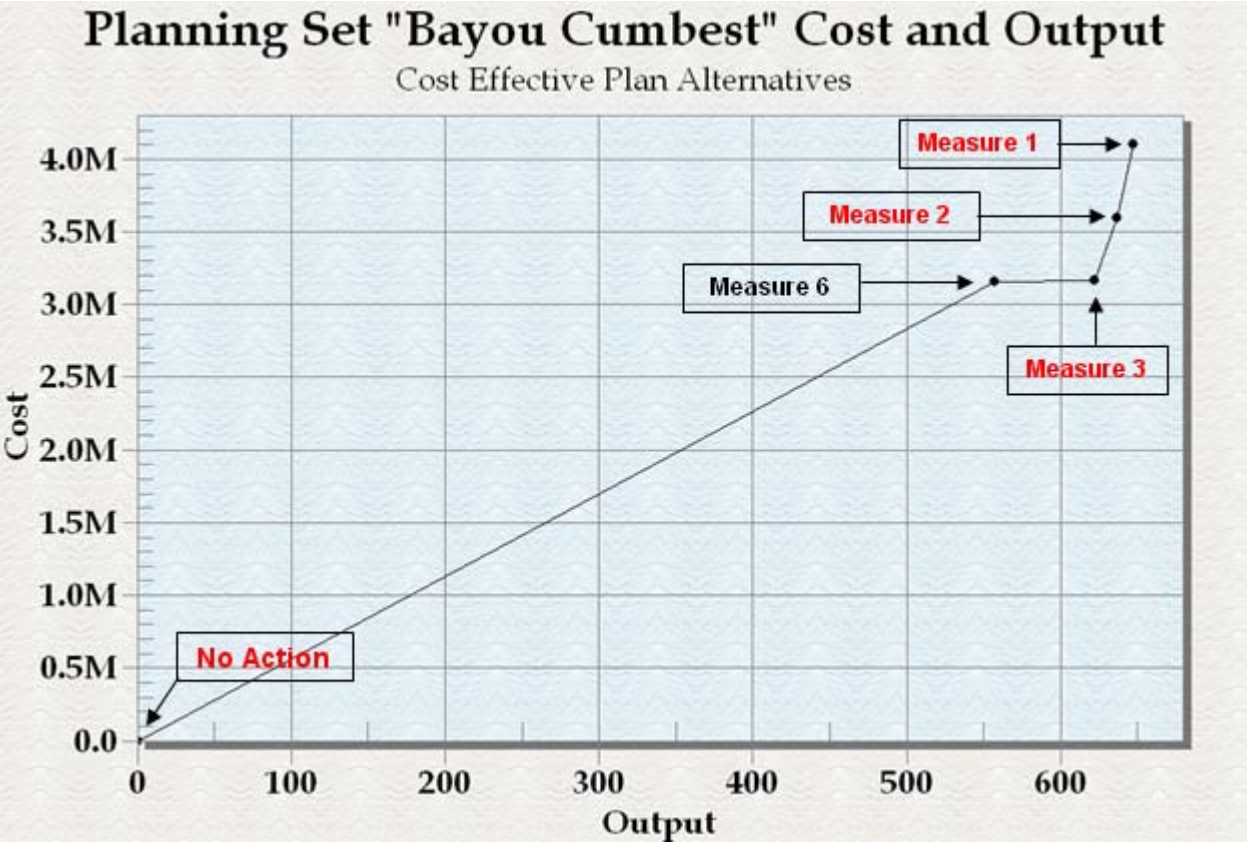

Figure 26 Cost Effective Measures (Plans) for Bayou Cumbest Area.

Plan 1 only produces slightly more benefits than Plan 2 and at a significant increase in cost. In addition, the MsCIP team has had found that the 1 meter spacing has a higher success rate than the 2 meter based on professional experience by the Corps, universities, NGOs, State, and other Federal agencies with restoration of similar emergent marsh habitats. Past experience in coastal Mississippi has proven that spacings, elevation, and hydrology are the three key essential components to obtain a successful emergent marsh site. The three spacing techniques (0.5, 1.0, and 2.0 meters) have been used recently at a local coastal Mississippi project on Deer Island in Harrison County. Although the 0.5 meter spacing may have a slightly higher success rate, the overall goal of the restoration project can be achieved by spacing the tidal emergent plants out to 1.0 meters per plant at a significant reduction in cost. The 2.0 meter spacing of Plan 3 was determined to leave the site too vulnerable to storms and/or hurricanes; thus, this spacing technique proofed to be rather risky.

The recommended plan (Plan 2) will restore 373 acres. The recommended plan consists of restoring the natural ecosystem by excavating old fill material, removing exotic plant species from non-excavated areas, filling existing artificial ditches, and planting native vegetation, such as *Spartina alterniflora* (Smooth Cordgrass) at the seaward edge of marsh; *Juncus roemerianus* (Black Needle Rush). The construction cost is estimated to be $58,700,000 with an annual average operation and maintenance cost of $372,000.

10.1.3 Admiral Island Ecosystem Restoration

The 118 acre restoration area is located in Hancock County adjacent to Bayou La Croix and near Bay of St. Louis (Figure 27). The property is owned and maintained by the State of Mississippi and consists of degraded wetland habitat as a result of debris and sediment deposited during the storm surge event of Hurricane Katrina.

Figure 27. Admiral Island Ecosystem Restoration Area

The tidal marshes in this area were ditched during the 1960s causing changes in the natural hydrology and subsequent changes in the species composition. Hurricane Katrina left extensive debris fields and sedimentation throughout the area and destroyed many native trees and vegetation. Due to the loss of native species, this area is experiencing a severe infestation of the invasive Chinese tallow tree, which is invading the marshes and the adjacent flatwoods. These exotic species outcompete the native vegetation, which provides food sources to the many fish and wildlife important species, including T&E species. Without any native competing species, these exotic species eventually become the only species in the area and result in a much degraded function of the wetlands.

Since the entire site is owned by the State and is not divided by any natural or manmade hydrologic divide, the entire site is evaluated with combinations of measures including no action, excavating old fill material, removing exotic species, and filling in the existing artificial ditches on the site.

The management measures were combined to create seven plans that were analyzed to determine the cost-effectiveness of each. Economically ineffective plans are identified and eliminated to determine which plans are cost-effective. An economically ineffective plan is a plan that cost more or the same as a subsequent plan but produces less benefit than that subsequent plan. Of the seven plans analyzed, Plans 4 and 5 were eliminated because they produced less benefit at greater cost than a subsequent plan (see Figure 28). The plans that were eliminated included leaving artificial ditches in place with native vegetation planted at 0.5 and 1.0 meter spacing.

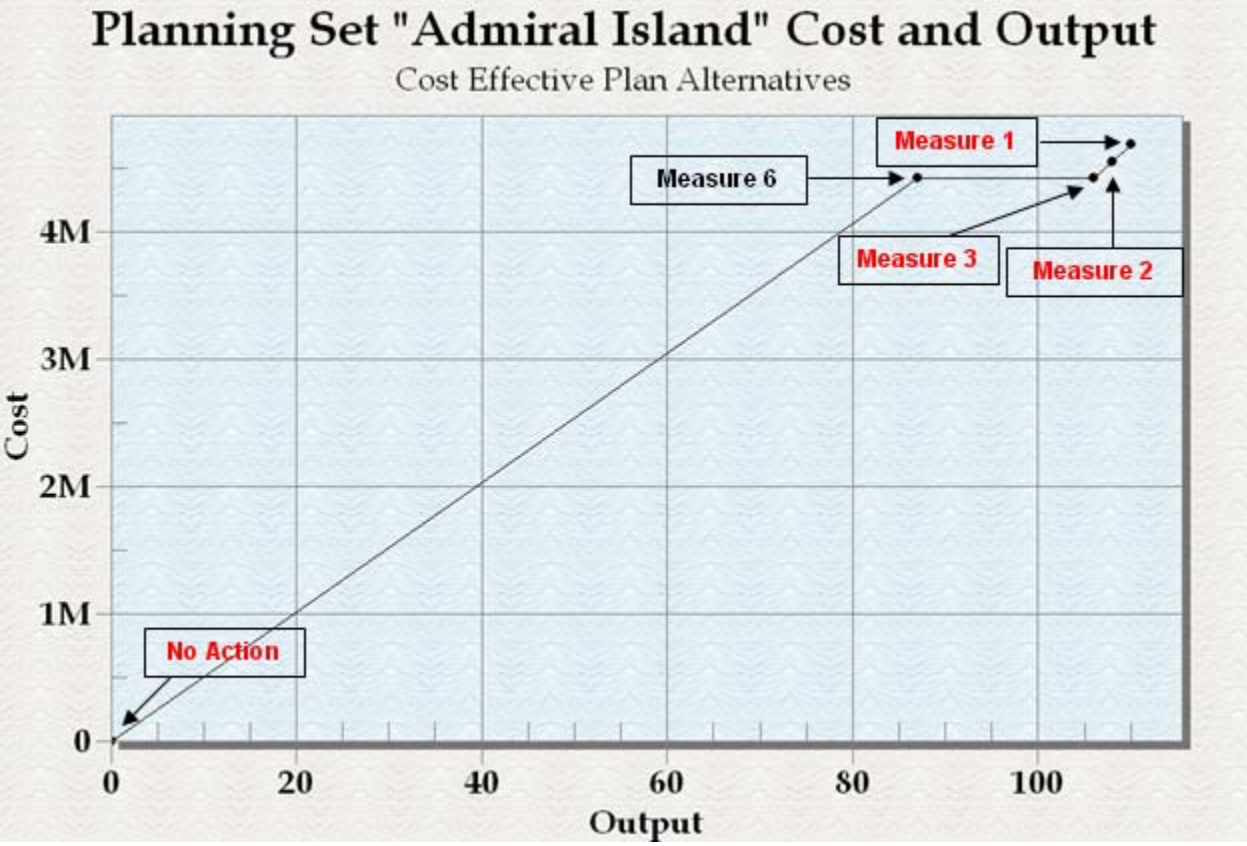

Figure 28 Display of Cost Effective Measures (Plans) for the Admiral Island Area.

Plan 1 only produces slightly more benefits than Plan 2 and at an increase in cost. In addition, the MsCIP team has had found that the 1 meter spacing has a higher success rate than the 2 meter spacing. The 2.0 meter spacing of Plan 3 was determined to leave the site too vulnerable to storms and/or hurricanes; thus, this spacing technique proofed to be rather risky.

The recommended plan (Plan 2) will restore 118 acres. The recommended plan consists of restoring the natural ecosystem by excavating old fill material, removing exotic plant species from non-excavated areas, filling existing artificial ditches, and planting native vegetation, such as *Spartina alterniflora* (Smooth Cordgrass) at the seaward edge of marsh; *Juncus roemerianus* (Black Needle Rush). The construction cost is estimated to be $38,400,000 with an annual average operation and maintenance cost of $114,000.

10.1.4 Dantzler Ecosystem Restoration

This 385-acre State-owned site is located in central Jackson County near the Pascagoula River (Figure 29).

Figure 29. Dantzler Ecosystem Restoration Area.

The site was planted in plantation pine during the 1960s and drainage ditches and stormwater lines were constructed in the early 1970s in anticipation of residential development of the site. The restorable area is split by a road, 151 of the acres are north of the road and the remaining 234 acres are south of the road. The long-term exclusion of fire and the invasion of non-native species, such as Cogon grass and Chinese tallow tree, have also severely degraded the site. These exotic species out compete the native vegetation, which provides food sources to the many fish and wildlife important species, including T&E species. Without any native competing species, these exotic species eventually become the only species in the area and result in a continuing degradation of the functional value of the wetlands. The importance of the wet pine savannah has been previously been discussed in the Turkey Creek ecosystem restoration project above.

Winds from Hurricane Katrina destroyed most if not all of the plantation pine leaving massive amounts of tree litter on the ground. In addition, debris and sedimentation resulting from the storm surge added even more litter. The exotics that were present in the site prior to the storm thrive in this type environment and it is likely that without restoration of the site they will become the dominant species inhabiting the site. Six alternative plans were developed to address the ecosystem restoration of the area.

The site is divided into two portions which could be addressed separately or in combination. Plans were evaluated on the basis of addressing the degraded nature of the entire site (385 acres), the northern portion of the site (151 acres), and the southern portion of the site (234 acres). Since the State is the owner of the site no lands would need to be acquired to accomplish this plan. The plans were also developed using a combination of measures including no action, maintaining native vegetation by burning or mowing, removing exotic vegetation, filling in artificial ditches.

These seven plans were analyzed to determine the cost-effectiveness of each. Economically ineffective plans were identified and eliminated to determine which plans are cost-effective. An economically ineffective plan is a plan that cost more or the same as a subsequent plan but produces less benefit than that subsequent plan. Of the seven plans analyzed, Plans 2, 4, and 6 were eliminated because they produced less benefit at greater cost than a subsequent plan. All three of the plans eliminated included the use of mowing as a management measure for restoring and/maintaining the wet pine savannah habitat. Of the three remaining plans, Plan 1 proved to be more cost-effective (see Figure 30) and consists of restoration of 385 acres of restoration maintained by burning. Details of the plan evaluation may be found in the Environmental Appendix to this report.

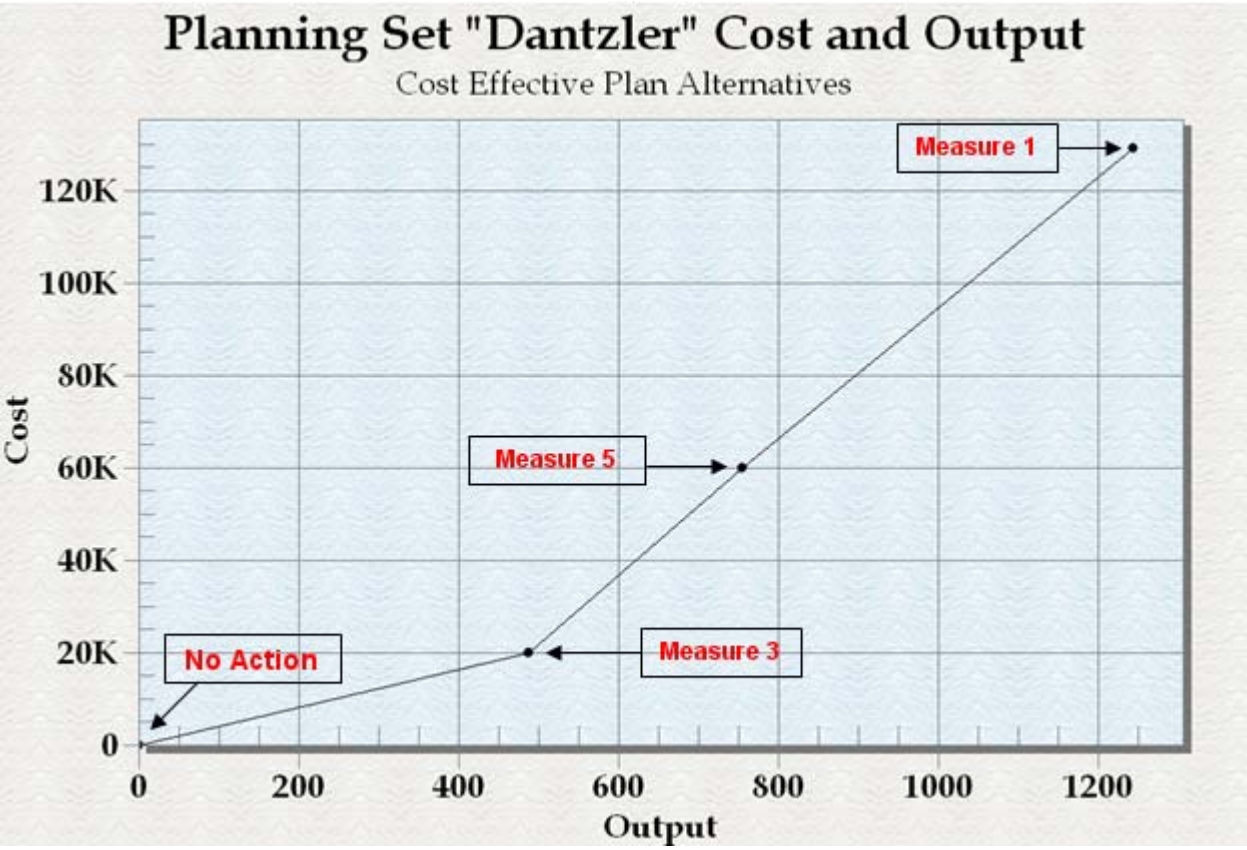

Figure 30. Display of Cost Effective Alternatives for the Dantzler Area.

An essential component necessary when selecting the recommended plan at for this restoration site was the need for burning. Burning allows the wet pine savannah environment to continue naturally as a functioning system. Although mowing does effectively keep understory plants from over

colonizing the area, it does not simulate the natural conditions (i.e. seed germination, heating the pine bark, etc.) Therefore Plan 1, with its burning measure, ranked higher than that of the mowing.

Plan 1 requires filling ditches, excavating and removing existing roadbeds and any additional fill, and maintaining vegetation growth by burning the project area in the initial year of construction as well as maintaining it by burning every three years over the life of the project as needed. As with the Turkey Creek ecosystem restoration, periodic burning of the site is a critical element to the success of the restoration. The cost of this plan is estimated to be $1,880,000 with an annual average operation and maintenance cost of $26,000.

10.1.5 Franklin Creek Ecosystem Restoration

The Franklin Creek ecosystem restoration area is located near the communities of Orange Grove and Pecan, Mississippi in eastern Jackson County, near the Mississippi - Alabama state line (see Figure 31). This area has already been funded for acquisition and demolition of 30 structures as part of the MsCIP Interim Report. The restoration area consists of 149 acres located north and south of U.S. Highway 90, a major thoroughfare through the community. This area routinely floods with only a slight rainfall; thus, this would also provide additional flood storage capacity by restoring the natural habitat. Pine savannah wetlands are commonly referred to as sponges that provide floodwater retention, groundwater recharge, and water purification. This wetland habitat is under increased developmental pressures due to the extreme and urgent housing need faced by Mississippians as they are trying to rebuild. This habitat is becoming fragmented and with the increased development, fire maintenance is increasingly harder to perform.

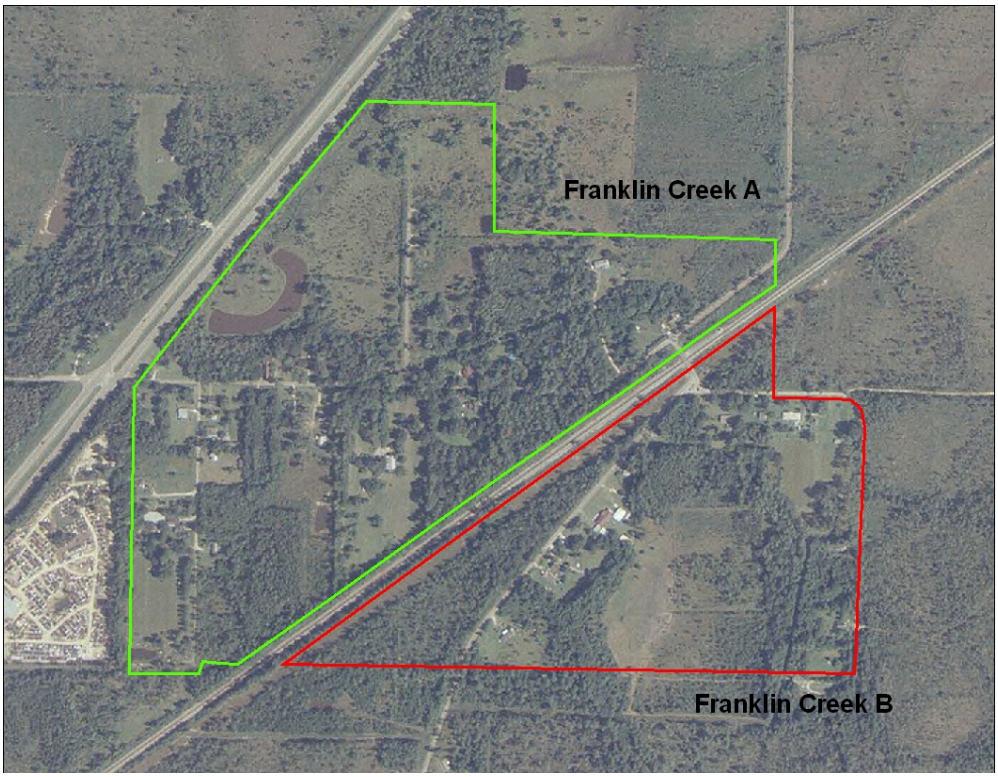

Figure 31. Franklin Creek Restoration Site.

Site evaluation options are limited to restoring the ecosystem of the entire 149 acre area or just restoring the portion of the site south of U.S. Highway 90 / L&N Railroad. Restoring the portion of the site north of the highway is not an option due to the frequent flooding of the area.

Five plans were created from a combination of measures including no action, maintaining native vegetation, excavating and removing roadbeds and fill material, filling in artificial ditches, and adding culverts to improve hydrology. The addition of culverts under the railroad berm is a necessary management measure in the restoration of the entire site as this would allow the flow of water from the frequently flooded northern area into the southern area for restoration of the natural hydrology. These plans were analyzed to determine the cost-effectiveness of each. Economically ineffective plans are identified and eliminated to determine which plans are cost-effective. An economically ineffective plan is a plan that cost more or the same as a subsequent plan but produces less benefit than that subsequent plan. Of the five plans analyzed, Plans 2 and 4 were eliminated because they produced less benefit at greater cost than a subsequent plan. These plans all involved maintenance of vegetation via mowing. Of the two remaining plans, Plan 1 proved to be by far the most cost effective and this recommended plan consists of restoration of 149 acres of restoration aided by managed water flow and maintained by burning.

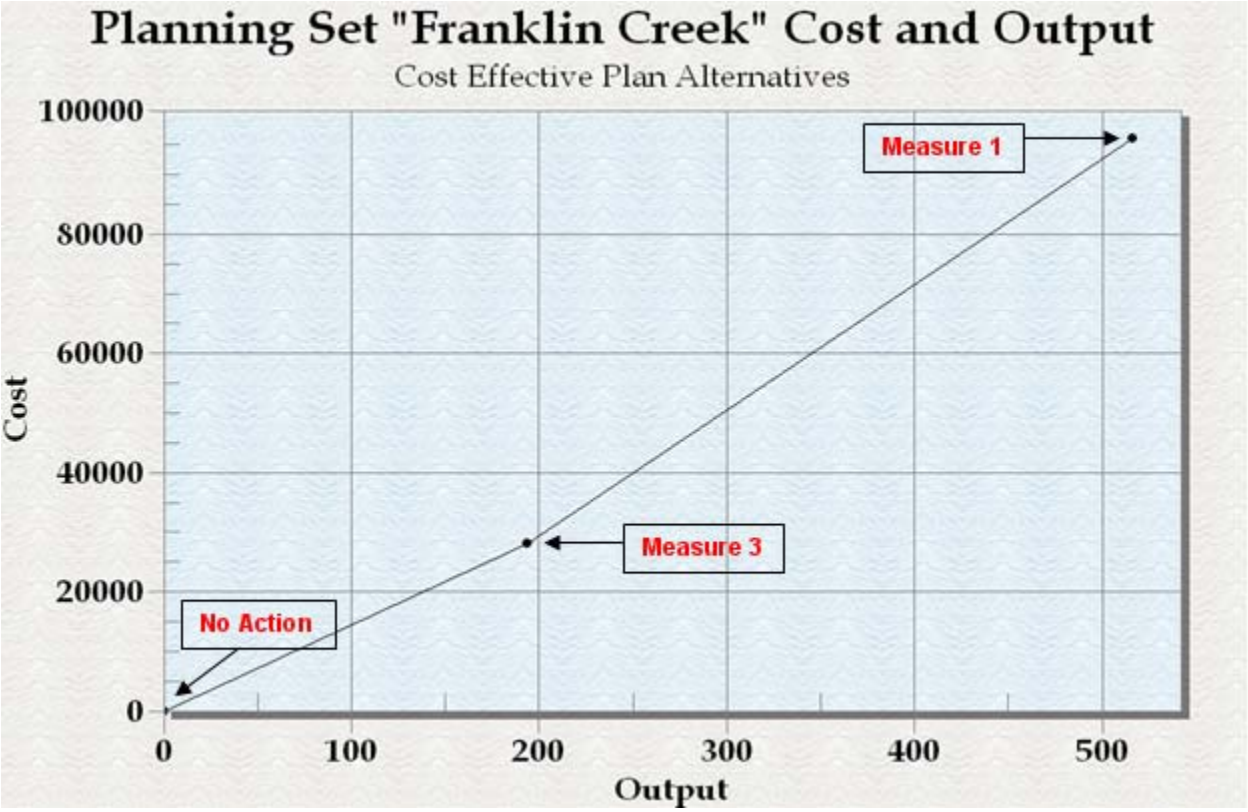

Figure 32. Display of Cost Effective Measures (Plans) for the Franklin Creek Area.

The recommended plan (Plan 1) requires filling ditches, excavating and removing existing roadbeds and any additional fill, installing culverts under the highway, and maintaining vegetation growth by burning and mowing the project area in the initial year of construction as well as maintaining it by burning every three years over the life of the project as needed. The cost of this plan is estimated to be $1,630,000 with an average annual operation and maintenance cost of $11,000 over the life of the project.

10.1.6 Moss Point Municipal Services Relocation

This report supports the recommendation for authorization to immediately implement the Moss Point Municipal Services Relocation component of the Comprehensive plan. The City of Moss Point is located north of the City of Pascagoula in Jackson County. All of the City's municipal services were disrupted by Hurricane Katrina, and their structures were either severely damaged or deemed uninhabitable. The MsCIP has formulated alternatives that would aid the city in providing basic community services in a more timely fashion after future storm events, and further demonstrate the effectiveness of relocations projects as a hurricane and storm damage reduction measure along the Mississippi coast. The best means of achieving these goals consists of relocating the city's municipal buildings to a lower risk site with regards to flooding within the incorporated limits. These buildings include the city hall, police station, fire station and community services building. Future use of the existing site of these buildings would be as open space that would provide a buffer between City and the Escatawpa River further reducing the damages from hurricane surge and flooding events.

The relocation of these facilities would greatly reduce future damages to the local infrastructure and provide a higher confidence in uninterrupted public service in future events. Regional economic benefits include an increase in sales volume of $20,250,000, a $4,286,426 increase in local income, and a net increase of 129 jobs. The construction cost of this project is $8,429,000. There are no operations and maintenance costs.

10.1.7 Waveland Floodproofing

This report supports the recommendation for authorization to immediately implement the flood proofing at Waveland, MS. The city of Waveland is located in Hancock County and was directly in the path of Hurricane Katrina. Because of the low lying nature of the city, the only flood damage reduction measures available to a portion of Waveland are either acquisition or floodproofing of individual structures. FEMA has released a manual for "Recommended Residential Construction for the Gulf Coast" which is meant to aid residents in rebuilding on strong and safe foundations. The design manual (FEMA 550) provides recommended foundation design and guidance for rebuilding homes destroyed by hurricanes in the Gulf Coast. The Waveland floodproofing alternatives are designed to evaluate the FEMA 550 guidelines with regards to current Corps' floodproofing practices. In addition to showing the application of existing elevation techniques and construction practices to reduce flood damages, this alternative would evaluate the use of possible innovative contracting techniques. These techniques would be designed to improve the Corps – contractor – homeowner relationship, focusing on using more timely and customer focused approaches. The 25 structures selected for floodproofing represent an adjacent group of structures that were not destroyed by Hurricane Katrina.

In order to evaluate the different foundation and building types, 25 structures would be selected in the Waveland area that could be safely elevated out of the 1% chance storm event, and which could not be protected by any other structural measures evaluated as part of this study. Damages to these structures would be significantly reduced and the area would serve as an example of smart growth. Regional economic benefits include an increase in sales volume of $20,250,000, a $4,286,426 increase in local income, and a net increase of 129 jobs. The construction cost is $3,130,000. There are no operations and maintenance costs.

10.1.8 SAV Restoration Pilot Project

Additional study is required to assess the complex environmental make-up impacting SAVs in Mississippi Sound due to the fact that mere planting would possibly not survive. Many questions must be answered (i.e. water quality, circulation, etc.) prior to SAV restoration implementation throughout the Mississippi sound. SAV restoration efforts across the nation have proven to be rather challenging and many examples can be identified close to Mississippi over in Florida. Therefore, the MsCIP team is recommending a pilot project in the Bayou Cumbest area. Opportunities exist to partner with Federal, state, and local resource agencies as well as NGOs. Extensive coordination with the NPS, responsible for managing and operating the Gulf Islands National Seashore, would be required for areas of potential restoration within their park boundaries. Involvement of local colleges and universities with ongoing research programs would also help to identify and pinpoint specific problems for development of potential solutions.

The first goal of this proposed community-based restoration pilot project in the Grand Bay National Estuarine Research Reserve (NERR) will result in restoration of up to 5 acres of *Ruppia maritima* resulting in the recovery of an equal amount of SAV habitat to that lost during the 2005 hurricane season. The second goal is to evaluate 3 restoration techniques to demonstrate their feasibility for larger restoration projects. The third and final goal to be achieved through volunteer involvement and educational outreach will increase awareness of the importance of SAV habitat in Mississippi Sound and provide coastal managers and restoration practitioners with the knowledge of techniques to maximize their return on dollars spent.

Three transplanting methods for restoring *R*. *maritima* will be evaluated as follows:1) direct planting from the donor site, 2) harvesting plant sprigs with one or more meristems (growth regions) from the donor site with subsequent growth in a greenhouse setting prior to planting, and 3) spreading seeds or mature flowering shoots over the restoration site. All plants and seeds would be acquired from a common donor site within the same system. After transplanting, quarterly monitoring for two years would be conducted to determine plant establishment, photosynthesis, growth, and expansion.

The education and outreach components of the project will consist of volunteer involvement and dissemination of results through a professional workshop conducted at the end of the project. Volunteers will be recruited from Grand Bay NERR's established volunteer base, which includes local schools, universities, agencies, and civic groups. This effort will help determine the most successful and cost- and labor-effective transplanting method for restoring SAV. Results will be disseminated through Grand Bay NERR's Coastal Training Program to inform coastal decision-makers and resource managers of successful restoration techniques.

This community restoration project will address the larger issue of SAV losses nationally and rates of natural recovery following disturbance versus recovery via restoration following disturbance. An estimated $500,000 would be required for the Bayou Cumbest SAV ecosystem restoration pilot and includes all effort associated with the planting and monitoring and producing a final restoration report.

10.1.9 Barrier Island Ecosystem Restoration

The barrier islands have historically constituted a barrier to saltwater, maintaining a careful balance of saltwater and freshwater flows, which sustain the valuable marine resources of Mississippi Sound. The barrier islands also provide a barrier to onshore movement of waves, and to a lesser extent storm surge, by attenuation.

Alternatives being evaluated include very limited restoration of Ship Island, only in the vicinity of the endangered cultural sites of Fort Massachusetts and French Warehouse, on (the post-Katrina

condition) “West” and “East” Ship Islands, respectively up to ‘massive’ restoration of the historic island dimensions. Although the protection of the cultural resource sites appears to be a justified option, this alternative would neither represent a complete solution, nor a completely effective means of addressing the larger problem faced on that island and the others. On the other hand, a more massive plan for barrier island restoration, or more direct application of sand, was rejected by many on the team, as unmanageable and potentially damaging, due to the unknown effects that might be introduced by placing sand into an area that could not be maintain by littoral drift over the long-term. More massive measures did not appear to provide a significantly greater volume of functional increase, for a much larger outlay of funds.

As part of the evaluation increasing the volumes of sand to the system is determined to be increasingly effective in achieving additional functional value, particularly when sand was provided directly into the littoral drift that created and nourishes the islands, so that “Mother Nature” can finish the job of distributing the sand in a natural way, to those areas of the island most suited to the current drift climate.

Several alternatives have been evaluated regarding the restoration of the Mississippi barrier islands. The most promising alternative for barrier island renourishment and protection of Mississippi Sound is the comprehensive plan. This plan would produce the greatest functional benefit per dollar expended, is a complete solution, represents an efficient use of Federal and local funds, is effective in its treatment of the problem (particularly in comparison to less effective structural wave reduction measures), and is acceptable to stakeholders in terms of existing laws, policies and priorities. In addition, the public is highly supportive of its measures to address the degradation of the barrier islands, as an element of a natural barrier to storms, and in the restoration of marine resources associated with Mississippi Sound.

This alternative includes the direct placement of sandy sediments to fill the breach in Ship Island and thereby reconnect West and East Ship Islands to their historic condition and to place sandy sediments within the littoral zones of Ship, Horn and Petit Bois Islands to ensure that the sediment budget of the islands is sufficient to maintain the islands in the future. This littoral zone placement would also benefit from the modification of dredging and disposal practices of the federally maintained Gulfport and Pascagoula Harbor navigation projects. These coupled efforts would begin the long-term process of barrier island repair and sustainability. Another consideration that still must be addressed is the best alternative for dealing with the erosion of Cat Island. This island is geomorphically different from the other 3 barrier islands and our understanding of the processes controlling Cat Island is not well developed. Additional effort would be required to add this island into an overall comprehensive barrier island restoration plan. The estimated construction cost of the barrier island comprehensive plan is $345,000,000 including the Cat Island study.

10.1.10 Forrest Heights Flood Damage Reduction

In Harrison County Mississippi the Forrest Heights community is located within the city of Gulfport at the lower end of the Turkey Creek floodplain and in a part of the larger historic Turkey creek community. Harrison County was over topped and heavily damaged by the hurricanes of 2005. Particularly, the storm surge and winds generated by Hurricane Katrina on August 29, 2005, caused structural damage to the existing levee that provides inland flood protection to this low lying residential community.

Storm surge inundation reached a depth of 2-8 ft over the entire community during Hurricane Katrina. In addition, prior to Hurricane Katrina, Forrest Heights was frequently inundated by flood waters due to inland flooding along the lower reach of Turkey Creek that overtopped the existing levee. An economically justified improvement to the existing earthen levee for inland flooding protection was evaluated in July 2005, prior to landfall of Hurricane Katrina. These evaluations

included 100-year, 250-year and 500-year protection and elevations up to 19.5 feet above sea level. This plan was put on hold following Katrina in order to evaluate suitable defense of Forrest Heights from hurricane storm surge flooding. The levee was evaluated at elevations 17 ft and 21 ft above sea level.

All evaluated alternatives were also gauged against the intent of Executive Order 12898, "Federal actions to address environmental justice in minority and low-income populations". Since the establishment of the Turkey Creek Community by freed slaves and their descendants, federally funded construction programs including the Gulfport Regional Airport, US Highway 49 and Interstate Highway - 10 have impacted the Turkey Creek Watershed. In addition, numerous other constructions including hotels, shopping centers and housing developments have been federally permitted to fill wetlands and construct within the Turkey Creek watershed.

Through modeling results, a levee height of approximately 21 feet above sea level was determined to be consistent with the levee certification guidelines with the basis measure being a storm surge elevation that has a 0.2% probability (500-year event) of occurrence in any given year. The levee is estimated to be 6,500 linear feet and require 93,000 cubic yards of fill. An existing park of 12 to 14 feet in elevation would serve as a water detention area for temporary containment of rainfall during storm events. The cost of this plan is estimated to be $ 9,000,000, with an average annual operating and maintenance cost of $ 77,000 over the 100-year life of the project.

10.1.11 High Hazard Area Risk Reduction Plan

The most effective alternative for reducing the risk from future hurricane surge events is to relocate structures and population from the high risk zones. Formulation of alternatives ranged from those which would provide for a minimum level of risk reduction (approximate base flood elevation) up to those that would provide for risk reduction from increasing levels of inundation. In addition an alternative concentrating on acquisition in the high to moderately high hazard areas was evaluated.

Hurricane Katrina destroyed an estimated 32,446 structures, which were "significantly" (i.e., 51% to 100%) damaged, and caused substantial damage to another 15,000 to 25,000 structures located within the inundation footprint of the three coastal counties in Mississippi. The vast majority of all destroyed homes within the inundation footprint have not yet been rebuilt, more than two years after the event. The rebuilding rate within the inundated area is much slower than might typically be expected following a hurricane. This is due in part to a significant increase in construction costs since Katrina, higher flood insurance rates and uncertainty resulting from the fact that FEMA has only in late 2008 released the revised Flood Insurance Rate Map (FIRM) and requirements outlining the elevation future first-floor construction must adhere to in order to qualify for flood insurance through the FIP. Limited rebuilding is occurring within the surge-plain, at a variety of elevations. Those that are rebuilding at former elevations are largely self-insured (or un-insured), while those rebuilding at higher elevations are doing so with an assumptions as to what the Base Flood Elevation (BFE) may be for their area. Regardless, most of those that would need flood insurance have not rebuilt at the time of this report, due to unavailability of that BFE data.

10.1.11.1 Phase I High Hazard Area Risk Reduction Plan (HARP)

Phase I involves the buyout of those properties that have been frequently flooded, or are at very high probability of future damage due to storm surge. The first phase of the HARP would include acquisition of approximately 2,000 properties which can be implemented over the next five years. Further information on the High Hazard Area Risk Reduction Plan can be found in the Nonstructural and Real Estate Appendices. The advantages of such a program are numerous including:

- Reduces future property loss and potential loss of life;

- Eliminates costly structural alternatives and associated long term operation and maintenance costs;
- Provides a buffer and aids in reducing storm surge to adjoining properties; and
- Provides a potential opportunity to initiate alternative uses of the acquired land for fish and wildlife, ecosystem restoration and public recreation.

Benefits of the program include reduction of future damages and risks to lives within those areas, and incidental recreation and social effects benefits. Select areas within certain acquired areas would be available for ecosystem restoration, and could also produce additional restoration benefits. Regional economic benefits include an increase in sales volume of $1,171,260,000, a $246,056,800 increase in local income, and a net increase of 7,213 jobs. The estimated costs for implementation of Phase I range between $187,500,000 and $397,000,000 depending on the ultimate number of parcels acquired and range of benefits provided under P.L. 91-646.

Prompt initiation of acquisition is more cost effective to the Government than commencing acquisition at a later date. Sensitivity analysis indicates that for every 1,000 previously-occupied parcels acquired prior to rebuilding, approximately $100 - $150 million could be saved by prompt acquisition, as compared to acquiring these same parcels after they are rebuilt. Acquisition prior to rebuilding avoids displacement impacts which increase significantly after residents have rebuilt. Near-term acquisition would reduce requirements for other Government-assisted temporary housing programs for those owners that might be still displaced, and would be continuing to receive financial assistance from the Federal Government.

10.1.11.2 Long-term High Hazard Area Risk Reduction Plan Evaluation

Evaluation of long term HARP is warranted to address the relocation of structures from the high to moderately high risk areas of the Mississippi coast. This program which could cover risk reduction opportunities over the next 20 to 40 years could target those properties which have been rebuilt but are still susceptible to significant future damage. A long-term HARP could involve the acquisition of large contiguous properties immediately following any large future hurricane events and be a joint effort between the USACE, FEMA, and the State of Mississippi.

The benefits of an ongoing acquisition and relocation program for coastal Mississippi could be tremendous taken into account the implications of sea level rise, continued development along the coast, and the frequency and magnitude of storms known to affect this area of the northern Gulf of Mexico. The additional study effort aimed at developing the framework and guidelines, detailed benefits, and costs would involve local and State interests as well as the Federal Emergency Management Agency.

Estimated study cost for development of a long-term HARP program is $5,000,000.

10.2 Studies Recommended for Finalization Under Programmatic Plan Authorization

Using the GIS based SDSS model, the MsCIP environmental team was able to effectively analyze needs in coastal Mississippi. A subset of potential restoration sites was identified by the SDSS tool and then ground-truthed by the MsCIP environmental team, including ERDC, Corps, MDMR, and USFWS. Using this interagency team allowed us to both confirm the accuracy of the SDSS results and to collect additional on-site information pertinent to restoration efforts. The MsCIP environmental team recommends immediate construction of the above 2 initial environmental restoration projects – Turkey Creek, Harrison County and Bayou Cumbest, Jackson County. In addition, the team

recommends potential environmental restoration projects specified in *Table 1.16.2.2-1* that would be studied further and restored under a MsCIP Environmental Restoration Programmatic Authority. The Environmental PDT anticipates studies, such as Project Information Reports (PIR), would range from $100,000 to $350,000 depending upon the specific project complexness. This cost has been incorporated into the cost-estimates. A rough order of magnitude cost-estimate has been prepared so that an upward construction budget is determined. The Environmental PDT will utilize the SDSS tool to prioritize environmental restoration site construction.

Development of partnerships with Federal resource agencies, state agencies, and NGOs is crucial to the success of this program. These partnerships would provide opportunities to access local knowledge of the existing environment. Specialists in specific restoration techniques would be available as well as opportunities to build on existing programs.

Once the restoration sites have been prioritized, a sequencing plan would need to be developed identifying the events necessary to accomplish restoration. This would ensure prioritized sites received immediate attention and further details developed for the required analysis. This plan would serve as an outline of the programmatic authority structure.

Once the PIR received approvals, a contracting mechanism would need to be put forward. The District PDT would need to incorporate Contracting Division in order to establish the most efficient type and beneficial use of contracting options and/or existing construction contracts. Oversight and quality assurance would ensure restoration was accomplished as envisioned.

Development of individual project monitoring plans should be incorporated into each restoration project. Adaptive management of ecosystem restoration projects, which would include the implementation of adaptive measures if required, would enhance the likelihood of the project achieving its goals and interim targets.

10.3 Additional Recommendations

While not compared in a system of accounts analysis, there are other areas that warrant either additional feasibility study or implementation by others. These include education on hurricane risk, hurricane and storm warning, evacuation plans, other structural measures, flood insurance, zoning changes, and saltwater intrusion plans. These are described in detail in the Main Report.

11 REGIONAL CONSIDERATIONS AND ACROSS-REGION INFLUENCES OF MSCIP AND LACPR ALTERNATIVES

11.1 MSCIP-LACPR COORDINATION ON REGIONAL ISSUES

11.1.1 Interaction/Coordination Between the Study Teams

The hurricanes of 2005 affected the entire region of the northern Gulf of Mexico from the panhandle of Florida to the Texas coast causing direct destruction to the immediate coast and its population centers. It also had unprecedented impacts to the much broader region from the subsequent migration of the affected population, wholesale disruption of the region's economy, disruption of the region's educational infrastructure, and untold impacts on the human resources of the region. In

essence, these impacts were not only local, but regional, and system wide as well. In its response to this disaster, the Congress of the United States authorized the U.S. Army Corps of Engineers (USACE) to initiate two important and comprehensive planning efforts to address the impacts caused by these storms and to plan actions that would make the region more resilient and less susceptible to future risk from such disasters. In formulating these actions, the USACE has taken a systematic and regional approach and has required that both the Louisiana Coastal Protection and Restoration (LaCPR) and Mississippi Coastal Improvements Program (MsCIP) efforts be fully coordinated with each other. In addition, both efforts used the same plan formulation strategy, as well as shared the use of the many technical tools required to perform the evaluations.

To this end, both teams are considering structural, nonstructural, and coastal restoration measures during the plan formulation. To ensure consistent communication and coordination, both teams have attended critical meetings regarding study goals and objectives, plan formulation, and Independent Technical and External Peer Review efforts. All modeling used in both efforts has been well coordinated, and both teams made use of, and jointly coordinated, the efforts of those USACE laboratories, Centers of Expertise, and ITR and EPR teams involved in these studies. In addition, the development of the Risk Informed Decision Framework (RIDF) has been a joint effort of the two studies.

All potential impacts, both adverse and beneficial impacts, are being considered without regard to geographic boundaries. Any measures which induce adverse impacts must be eliminated from further consideration or their impacts satisfactorily mitigated on a regional basis. Several measures may have beneficial impacts outside specific study boundaries. For example, the diversion of freshwater from the Mississippi River to Lake Borgne via the Violet marsh area could not only reduce saltwater intrusion in the Mississippi Sound south of Hancock County, but it could also provide much needed sediments to the Biloxi marshes of Louisiana. Also, the systematic restoration of the coastal sediment budget and sand transport system along the Mississippi barrier islands could provide benefits to eastern Louisiana.

11.1.2 Identification of Key Regional Issues

There are several key issues that are common to both Mississippi and Louisiana. These include problems with shoreline erosion, wetlands loss, salinity intrusion, and storm surge and waves. Besides the obvious economic and societal impacts associated with hurricanes, both states have a significant problem with eroding barrier islands. These islands reduce wave energy and help significantly in reducing erosion to the mainland. The loss of wetlands along the coast is also a critical issue. Wetlands, including marshes and near shore marine and estuarine habitat, are the nursery grounds for the entire marine food chain in the Gulf of Mexico. And, like the barrier islands, they also help to reduce wave energy. Linked to both the degradation and loss of the wetlands and barrier islands is the increase of salinity in the estuarine areas of the Mississippi, Breton, and Chandeleur Sounds. These increasingly scarce areas of the United States require a delicate mix of fresh and salt water to provide habitat for oysters, shrimp, sturgeon, and other fisheries which also provide an important economic source for both states. Both LaCPR and MsCIP teams are working together to solve these issues at the local, regional, and national levels. Multiple focus groups, public meetings, and regional workshops have been held to make sure that the solutions presented in this report are comprehensive in nature, and also maintain the delicate balance between people and their environment.

11.1.3 Coordination with FEMA

In addition to the significant coordination between the MsCIP and LACPR teams, the teams have also coordinated fully with the Federal Emergency Management Agency (FEMA) to ensure a unified

approach in the development of appropriate hurricane and storm damage reduction alternatives. FEMA has different regional offices to manage different areas of the United States. FEMA Region IV serves the state of Mississippi, and FEMA Region VI serves the State of Louisiana. After Katrina, Regions IV and VI began the complex process of updating their Flood Insurance Rate Maps (FIRMS) to include storm surge. FEMA Region VI utilized the Corps, New Orleans District to provide the model for updating their FIRMS, while Region IV contracted with an Architect-Engineer firm for this effort. Both the MsCIP and LACPR teams employed a consistent methodology for storm surge modeling, and coordinated their efforts closely with both FEMA regions. FEMA Region IV's contractor adopted some slight differences in terms of the specifics of their modeling approach; however, the agencies reconciled the differences in water levels generated for Regions IV and VI, and used an averaging technique to achieve a unified approach and result.

11.2 REGIONAL STORM SURGE AND WAVE MODELING

11.2.1 Interaction of Storm Surge and Waves with Coastal Protection Measures

Large-scale levee systems; other man-made barriers; restoration of barrier islands that involve substantial increases in an island's cross section, crest elevation or length; or wetland restoration on a massive scale, all have the potential to influence storm surge levels and wave conditions produced by extreme hurricanes on a regional scale. Levees and barriers are intended to protect against storm surge, but they also can cause a build-up of storm surge by obstructing or completely blocking the movement of water that is driven by hurricane-force winds. The pocket formed by the natural barriers of the Mississippi coast, the Mississippi River delta, and, when the wetlands of the delta become inundated, the levee systems along the Mississippi River facilitates a build-up of storm surge as winds push water into the pocket. Barrier islands alter the movement of water toward the coast, providing some blocking action and by forcing the water to move through gaps between islands, an effect that is lessened once the storm surge overtops an island. The enhanced roughness of wetlands can slow the advance of storm surge somewhat, which can cause a small local increase in storm surge seaward of the wetland and slightly reduce the surge landward of the wetland or slow its arrival time slightly. Each of these processes might tend to retard the storm surge propagation in one area; but in the process of slowing the storm surge advance, the movement of water might be slightly redirected toward another location causing a local storm surge increase elsewhere. Natural and man-made protection and buffering features like wetlands and barrier islands do not decrease the mass of water driven into the region by the hurricane winds (mass is conserved); however, they do change the momentum and redistribute the storm surge.

Natural and man-made coastal protection measures can also significantly alter wave conditions during hurricanes, reducing the potential for wave-induced damage along the coastline during elevated storm surge levels. Levees and barriers can completely block wave energy; and barrier islands act to block ocean waves from reaching the mainland coastline or reduce wave energy. Even though the reduction is less, barrier islands greatly reduce ocean wave energy even when the surge has overtopped the barrier island. Wetlands reduce wave energy, although it is difficult to accurately quantify the reduction given the current lack of detailed knowledge about the physics of this process.

In both the MsCIP and LaCPR studies, the regional influences of several proposed project alternatives on storm surge levels were examined with regional storm surge and wave modeling. The regional surge/wave model was specifically designed with this requirement in mind by having model domains and grid meshes that encompassed both Louisiana and Mississippi, and by developing the models consistently (for example, adoption of similar grid resolution throughout the

model domain). The process for developing the regional model is briefly described below. Additional details can be found in appropriate appendices to the LaCPR and MsCIP reports (cite references to those appendices).

11.2.2 Initial Model Development by the IPET

As part of Interagency Performance Evaluation Task Force (IPET) work to examine the response of the southeast Louisianan hurricane protection system to Hurricane Katrina, regional storm surge and wave models were set up and applied for the coasts of Mississippi and Louisiana. The suite of models included ADCIRC, the regional storm surge model, WAM, the offshore wave model (a basin-scale wave model covering the entire Gulf-of-Mexico), and overlapping STWAVE shallow-water wave models for the complete nearshore zone spanning both states. The ADCIRC and STWAVE models were coupled to treat the very important interactions between waves and storm surge. Coupling was done to maximize accuracy of the regional models.

The IPET was a community effort, drawing on experts from several federal agencies (including the USACE, FEMA, NOAA, and the USGS), state agencies, the private sector, and academia. The work involved considerable sharing of data, model technology, and expertise among all the agencies, groups, and individuals involved. Work of the IPET was reviewed by two panels: one assembled by the American Society of Civil Engineers and the other by the National Research Council. Both panels included experts from the public and private sectors, and each was comprised of individuals representing a wide range of technical disciplines. Both review panels gave extremely high marks to the regional storm surge and wave modeling approaches used by the IPET.

11.2.3 Regional Consistency Between the LaCPR and MsCIP Projects

A collaborative effort was undertaken to meet the storm surge and wave modeling needs of both the USACE MsCIP and LaCPR studies and the FEMA work to update flood insurance rate maps for the region. The MsCIP and LaCPR studies required storm surge and wave modeling for the entire coastline of both states. The IPET modeling had focused only on southeastern Louisiana and western Mississippi. Therefore, the regional storm surge and wave models that were initially developed by the IPET were expanded and refined with higher model resolution to create regional models that spanned the entire Louisiana and Mississippi coastal zone. The linked ADCIRC and STWAVE models are completely consistent from the perspectives of regional model resolution, level of model detail, and input data quality. Higher resolution enables: (1) a more detailed representation of the landscape features that influence surge and wave propagation and coastal flooding, and (2) a more accurate representation of certain wave and surge physical processes. Model accuracy is directly related to model resolution. Figure 11.2.3-1 shows the portion of the regional ADCIRC storm surge model domain for the Mississippi/Louisiana coastal region, and Figure 11.2.3-2 shows the overlapping regional STWAVE model domains.

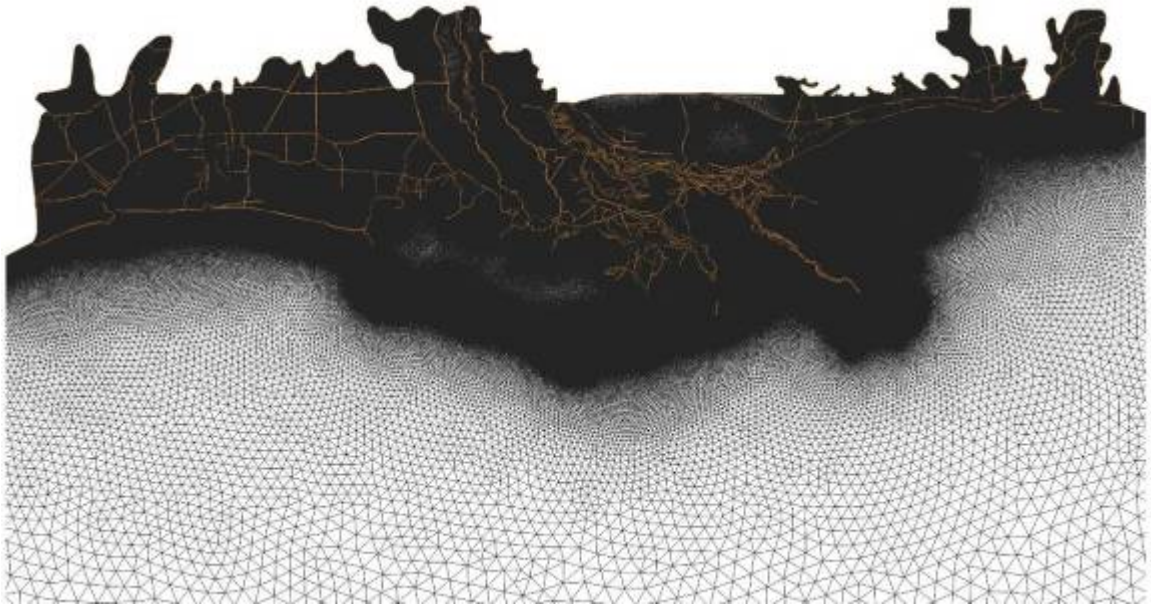

Figure 11.2.3-1. Representation of the Mississippi/Louisiana coastal region in the regional ADCIRC storm surge model

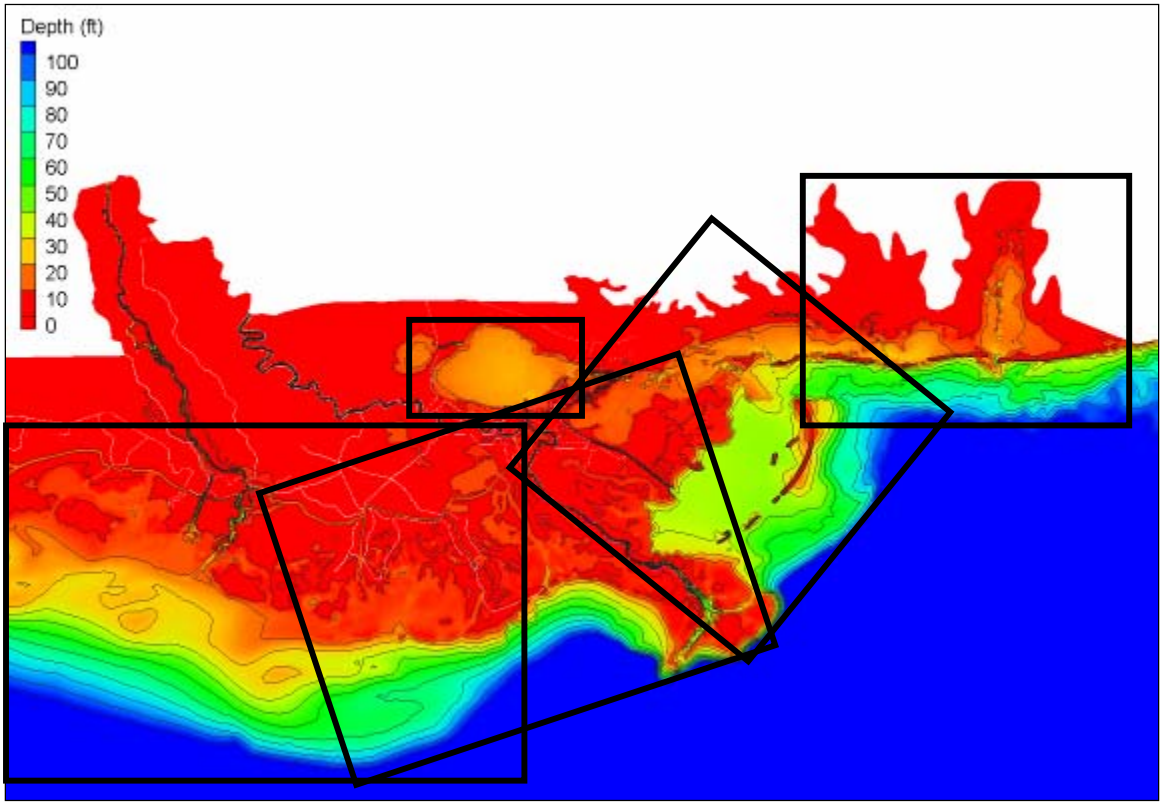

Figure 11.2.3-2. Overlapping STWAVE shallow water wave model domains spanning the Louisiana and Mississippi coasts (only the eastern portion of the westernmost Louisiana STWAVE model domain is shown here)

11.2.4 Hurricane Hazard Definition

In addition to having a regional-scale and regionally-consistent storm surge/wave model, a regionally consistent definition of the hurricane hazard was also important. A multi-disciplinary team, the Risk Assessment Group (RAG), was assembled by the Corps to characterize the probabilities of different hurricanes that can impact the northern Gulf of Mexico region. Their work fully utilized the best of today's knowledge, data and technology. Many of those involved in the work of the IPET contributed to the RAG, along with others from around the country (including members from NOAA and FEMA), in the same community spirit as the IPET. Consequently, results generated by the RAG have strong technical credibility and inter-agency acceptance. A significant achievement of the RAG, which supported both the MsCIP and LaCPR work and FEMA's remapping efforts, was the adoption of a unified general coastal flooding methodology that is being applied by USACE and FEMA. The unified approach involves coupled regional storm surge and nearshore wave models, the same approach originally taken by the IPET. The RAG developed a number of new insights into the behavior of hurricanes. One notable and extremely important finding was the tendency for all major intense hurricanes to decrease in intensity prior to landfall. The RAG developed a regionally-consistent Joint Probability Method-Optimal Sampling approach (JPM-OS) for defining hurricane probabilities and for calculating probabilities associated with hurricanes having a certain set of characteristics (track, intensity, size, forward speed). Figure 11.2.5.2-1 shows an estimate of the frequency of occurrence for major hurricanes in the north central Gulf of Mexico that was produced by the RAG. The figure shows the relatively higher probability of severe hurricane occurrence for southeastern Louisiana and Mississippi, relative to the probability of occurrence elsewhere in the Gulf of Mexico.

11.2.5 Corps-FEMA Coordination in Louisiana and Mississippi - Consistency of Hurricane Frequency Estimates

11.2.5.1 Development of Louisiana Data

Both FEMA Region VI and USACE employed the ADCIRC-WAM-STWAVE regional storm surge and wave model described above and the JPM-OS approach recommended by the RAG. The same set of model results was used in both the LaCPR work and in the FEMA Region VI remapping effort to characterize the hurricane hazard.

11.2.5.2 Development of Mississippi Data

Storm surge and wave modeling done for the MsCIP study was performed by USACE using the same regional modeling methodology as the LaCPR study (the approach outlined above). The MsCIP modeling work was coordinated with FEMA Region IV. However, results for the MsCIP project were required well before final numbers would become available from the FEMA contractor (URS Corporation) working on Region IV remapping. URS used a similar coupled surge and wave modeling

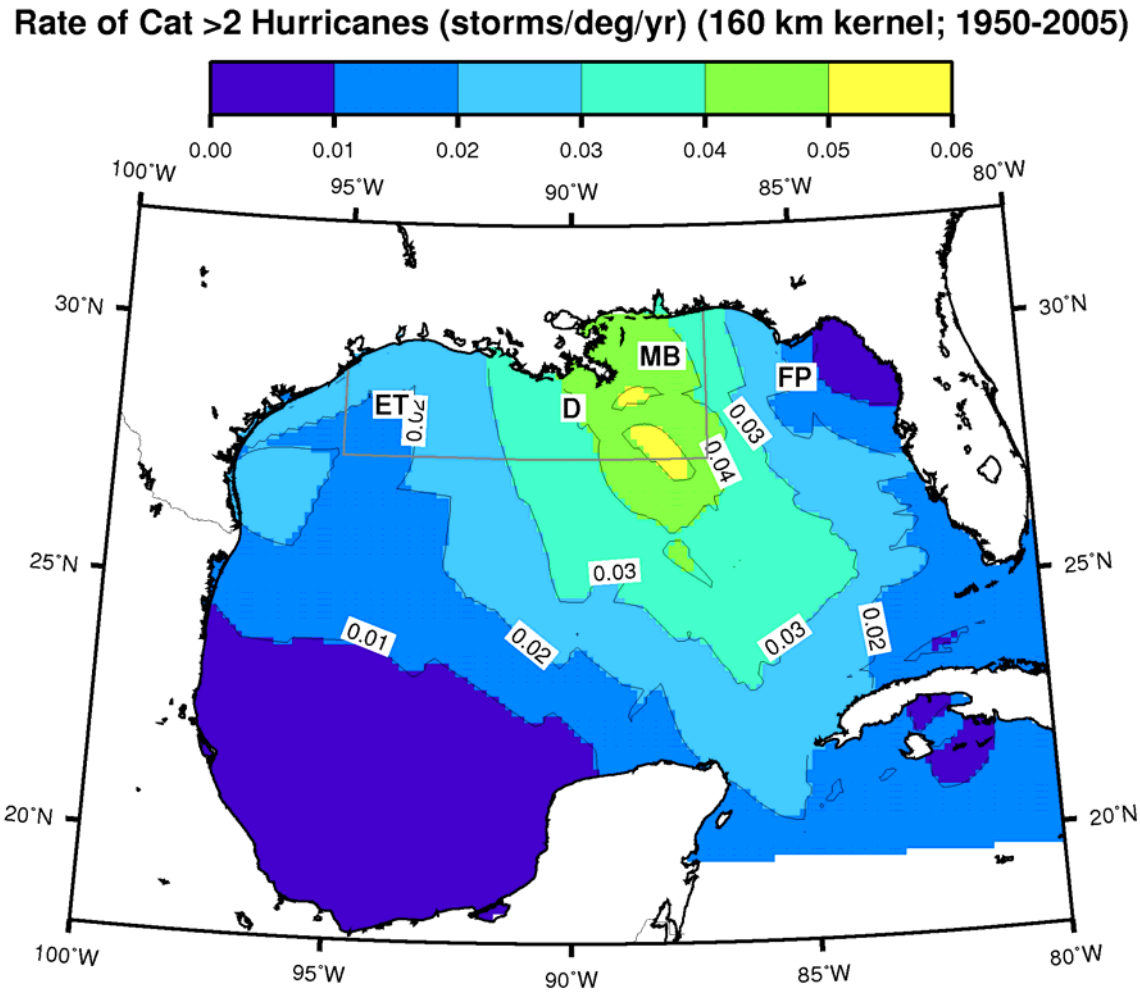

Figure 11.2.5.2-1. Analysis of hurricane frequency from Toro (Risk Engineering) from an analysis using an optimized spatial kernel (from the White Paper on Estimating Hurricane Inundation Probabilities by Resio et. al. 2006)

methodology but used the nearshore wave model SWAN, whereas USACE used the STWAVE model. However, the biggest difference in the approach used by the FEMA contractor was not in the modeling methodology, but rather in the specification of storm parameters and in the statistical computations. The FEMA Region IV/URS effort used different storm parameters and a different landfall (more inland) than USACE, which resulted in less pre- and post-landfall filling (i.e. less weakening) of the storms. In essence this resulted in stronger storms, producing higher water levels than those calculated by USACE. The agencies met and reconciled the differences in water levels for the Mississippi Gulf Coast through an averaging technique to achieve a unified Federal government set of results. Thus, there is a single Federal number for water levels corresponding to certain return periods. However, it should be noted that much of the MsCIP work proceeded with the preliminary values computed by the Corps to meet the Congressional schedule. The vast majority of storm surge-frequency curves computed by USACE and the FEMA contractor were within +/- 1 ft across the Mississippi coast. This is within the level of accuracy expected from these types of storm surge simulation models.

11.2.6 Comparison: Mississippi and Louisiana Data

When the Mississippi storm modeling results were compared to the Louisiana results near the Louisiana-Mississippi border, the Mississippi FEMA approach resulted in higher elevations around the state line than those resulting from the approach used by the LaCPR and FEMA Region VI studies. To resolve the issue, the USACE Engineer Research and Development Center (ERDC) provided a "blending algorithm" to achieve a smooth transition. As a result, the predicted still water elevations in the vicinity of the MS-LA border, corresponding to certain frequencies of occurrence, are considered scientifically accurate.

11.2.7 Present State of the Regional Storm Surge and Wave Model

A completely coupled and consistent regional storm surge and wave modeling capability is available to examine the regional influences associated with planned and proposed project alternatives being developed in the LaCPR and MsCIP studies, but only from the perspectives of project influences on storm surge levels and wave conditions. The model is based on the coupled ADCIRC-STWAVE models that were described above. The regional surge and wave model has been extensively validated using measured data acquired during Hurricanes Katrina and Rita, during the IPET and MsCIP and LaCPR projects.

This regional modeling capability was applied to examine regional-scale changes to storm surge levels associated with several of the proposed project alternatives, for example the influence of proposed barriers across Lake Pontchartrain on storm surge levels along coastal Mississippi, the influence of widespread Louisiana wetland restoration on storm surge levels in Mississippi, and the influence of Mississippi barrier island restoration on storm surges in Louisiana. Results from these applications are presented later in this chapter.

11.3 REGIONAL SALINITY/WATER QUALITY MODELING

In addition to regional influences on storm surge and waves, construction of large-scale levee systems or other man-made barriers, restoration of barrier islands that might involve increasing an island's footprint or length, or wetland restoration on a large scale, all have the potential to influence water exchanges and current patterns during normal tidal action and typical wind conditions. Such persistent changes to the hydrodynamic regime can alter salinity and water quality regimes leading to changes to habitat. These types of influences have not yet been examined in detail in either the LaCPR or MsCIP studies.

Wetland restoration measures proposed for construction in the MsCIP study are relatively small-scale features within small estuaries, and the barrier island changes proposed for construction in the MsCIP study do not involve significant changes to the barrier island footprints. Therefore regional-scale influences on salinity and water quality due to these alternatives are not expected to be significant. Wetland restoration and barrier island restoration at a much larger and widespread scale are being considered in the LaCPR study. These restoration measures can induce significant regional changes in terms of salinity, water quality and habitat and, therefore, will be examined in more detail in the future.

11.3.1 Consideration of Freshwater Diversions

Several alternatives are presently being considered in both the MsCIP and LaCPR studies to divert freshwater from the Mississippi River or other sources as a mechanism for promoting a reversal of a historic increase in salinity in the Mississippi Sound/Biloxi Marsh area. The intent of the diversion is to build wetlands, support fresher marshes and improve oyster reef health and productivity thus

enhancing both their economic value and the ecological services they provide. However, the water diverted from riverine sources not only has lower salinity, but usually carries more sediment and nutrients than marine water. Diversions may result in areas of excess nutrients and thus cause algal blooms and eutrophication, greater light attenuation, and changed substrate characteristics, so their system-wide impacts need to be carefully evaluated. Spatially-explicit evaluations of habitat change over large areas are required for such system-wide impacts.

Stated goals for the freshwater diversions in the lower Mississippi River/Mississippi Sound area include the following:

1) The enhancement of oyster resources in the Bay St. Louis area;

2) Desire to maintain oyster and shellfish resources in the Lake Borgne area;

3) The return of the ecosystem to historical salinity conditions;

4) The utilization of Mississippi River sediments to build and support wetland development;

5) The return of wetlands to a “fresher” condition, with particular emphasis in restoring areas of historical cypress forests.

These goals may in fact compete with one another, and may not be able to be met simultaneously. In addition, other competing resources in the system include the presence and location of shrimp fisheries, the survival and restoration of seagrass beds and the presence and survival of gulf sturgeon, a federally-listed, threatened subspecies. Therefore, any proposed diversion alternative needs to be carefully evaluated in order to fully understand the positive and negative aspects of various diversion scenarios and to assess their ability to meet any or some of the goals listed above.

11.3.2 Initial Model Development

To initiate evaluation of freshwater diversions, a regional water quality model (WQM) has been developed. The WQM, which is based on the CE-QUAL-ICM water quality model code, has been coupled to output from a three-dimensional hydrodynamic model of the region, which is based on the CH3D hydrodynamic model. The horizontal model grid (see Figure 11.3.3-1) extends seaward beyond the Chandeleur Island and includes Mobile Bay, Lake Borgne, Lake Pontchartrain, the Inner Harbor Navigation Channel of New Orleans and the Mississippi River Gulf Outlet Channel; and it includes all the major tributaries that introduce fresh water into the system, from the Tickfaw and Amite Rivers west of Lake Pontchartrain to the Mobile River in the east end of the grid. The model simulates changes in water quality constituents, including nutrients, phytoplankton, dissolved oxygen, temperature, salinity, and underwater light intensity.

11.3.3 Present State of the Regional Salinity/Water Quality Model

The regional salinity and water quality model has been extensively validated for the Mississippi Sound region, as part of previous work done by the ERDC and Mobile District. The model has not yet been as extensively validated for the Lake Pontchartrain and Biloxi Marsh areas; however, in light of past experience with the model in numerous studies, it is expected that the current state of the model is yielding reasonable results in this region for the purposes of the screening-level studies that have been conducted to date to examine the possible benefits of freshwater diversions.

To more accurately answer detailed questions about changes to salinity and water quality, and to answer them with greater confidence (a level which can withstand a high

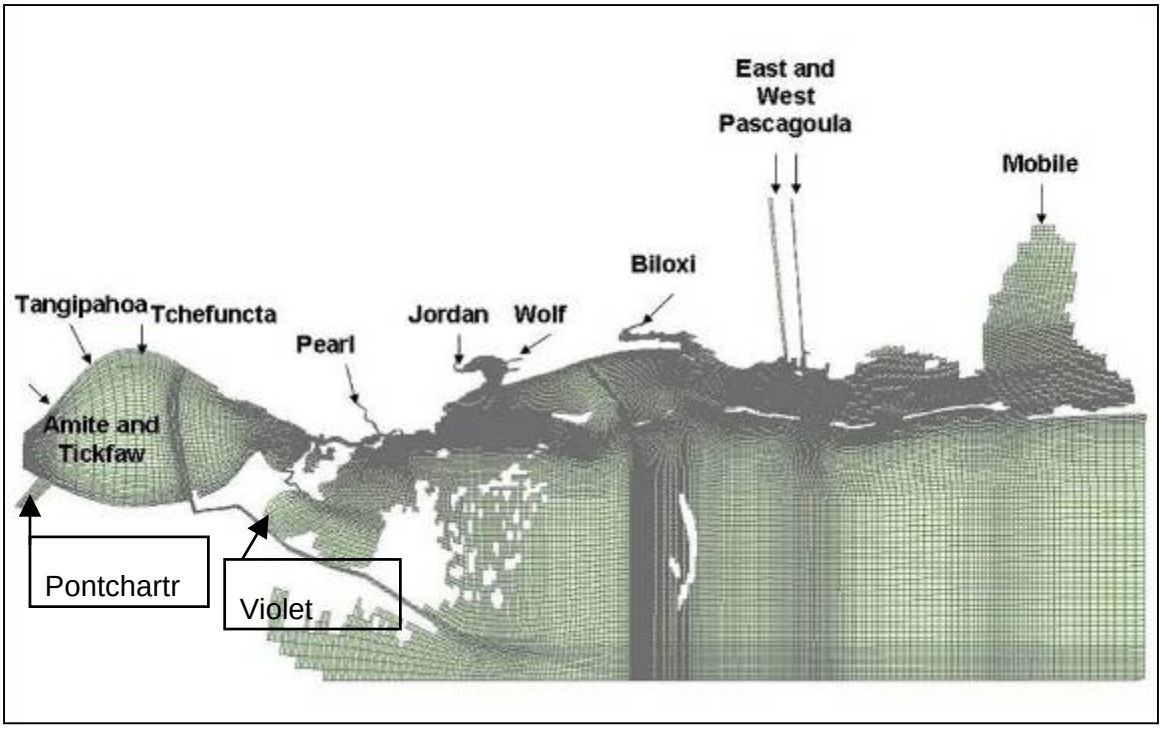

Figure 11.3.3-1. The model domain for the 3-D current hydrodynamic/water quality model, WQM

level of technical scrutiny), additional resolution and model refinement and validation, is needed. To answer more detailed questions about how changes in sedimentation, salinity and water quality translate to changes in landscape and habitat, additional model development, testing, and validation will be required. Requirements are discussed later in this chapter where the path ahead is discussed. Also note that the WQM model domain does not cover the entire coast of Louisiana. To properly examine questions regarding regional salinity, water quality and habitat questions throughout coastal Louisiana, the regional water quality model would have to be extended into those areas with a consistent level of resolution and detail, and be developed further in concert with work that is underway by Louisiana State University on habitat and ecological responses. For example, there might be regional influences in Texas associated with alternatives that are developed for western Louisiana. The need for expansion of the model will depend on the specific project alternatives that surface as preferred alternatives within the LaCPR study.

To date, the WQM has been applied to examine freshwater diversions at three locations: (1) diversion from the Mississippi River at Violet Marsh, (2) diversion of all of the Escatawpa River flow into Grand Bay, and (3) diversion from the Mississippi River at Bonnet Carre' spillway. Locations of these three diversions are shown in Figure 11.3.3-1 (annotated with boxes). Results were evaluated for several scenarios and compared to modeled existing baseline conditions to assess relative changes in the various water quality parameters. Results from these applications are discussed later in the chapter.

11.3.4 PRELINARY ASSESSMENT OF ACROSS-REGION INFLUENCES

11.3.4.1 Lake Pontchartrain Surge Reduction plan.

In general, there were four ADCIRC grids (levee alignments) used to investigate the feasibility of blocking or reducing the storm surges from entering Lake Pontchartrain via the tidal passes from Lake Borgne to Lake Pontchartrain and via overtopping of the land bridge that separates Lake Pontchartrain from Lake Borgne. The ADCIRC grids were designated as Grids A, B, C and D. See Figures 11.3.4.1-1 through 11.3.4.1-4.

Grid A was developed essentially as a theoretical plan that was designed to study the maximum reduction in surge responses in Lake Pontchartrain by eliminating any inflow into Lake Pontchartrain regardless of the intensity and surge heights in Lake Borgne. The features of this plan called for non-overtopping gated closure structures in the Chef and Rigolets Passes and connecting levees that were set sufficiently high so as to prevent overtopping from any of the storms used in the JPM-OS application. Grid A therefore isolated Lake Pontchartrain from having additional water volumes inflowing into the lake and restricted surge responses in the lake to the maximum extent possible.

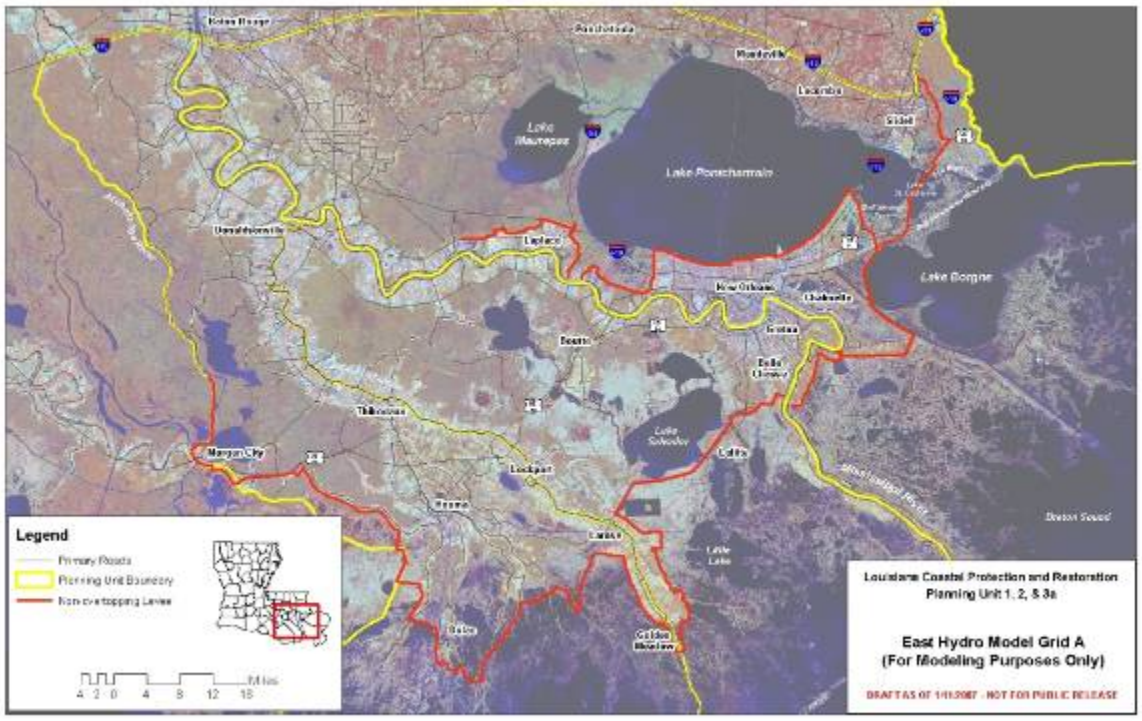

Figure 11.3.4.1-1. LACPR Model Grid A

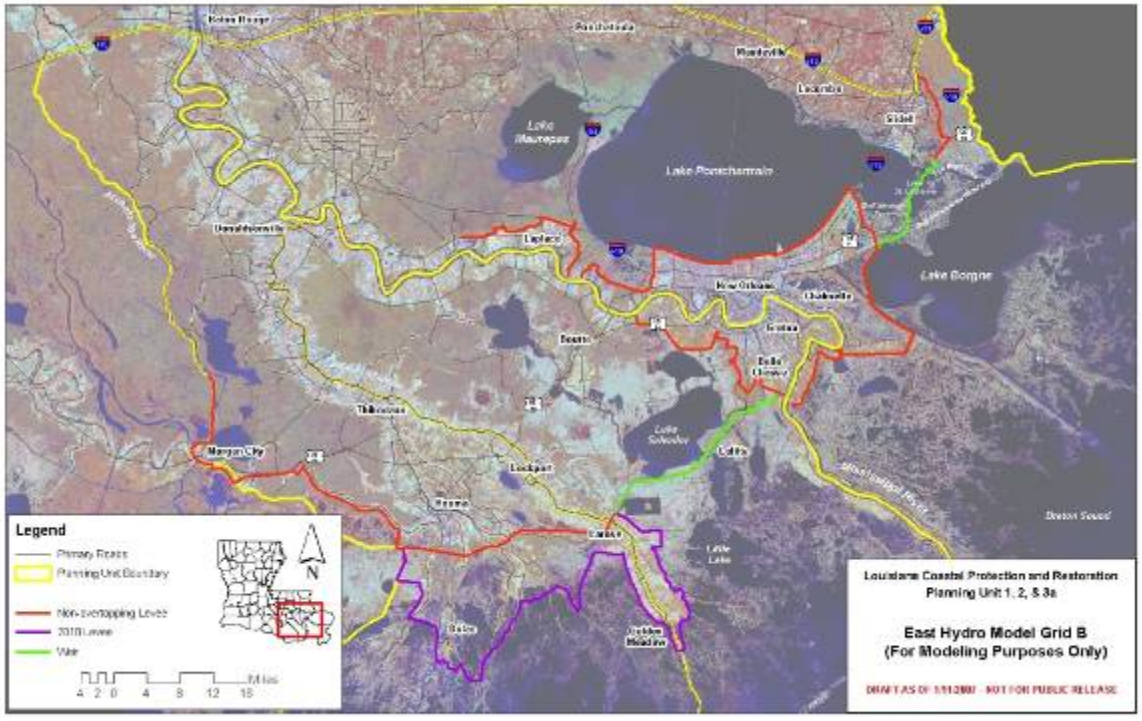

Figure 11.3.4.1-2. LACPR Model Grid B

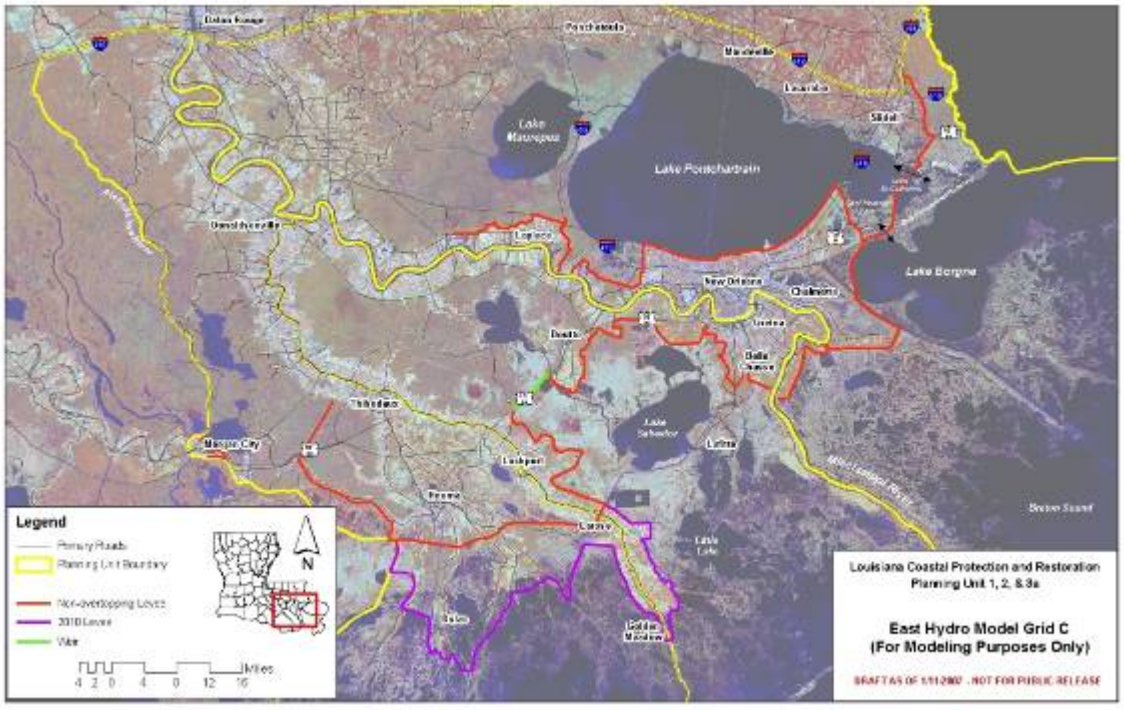

Figure 11.3.4.1-3. LACPR Model Grid C

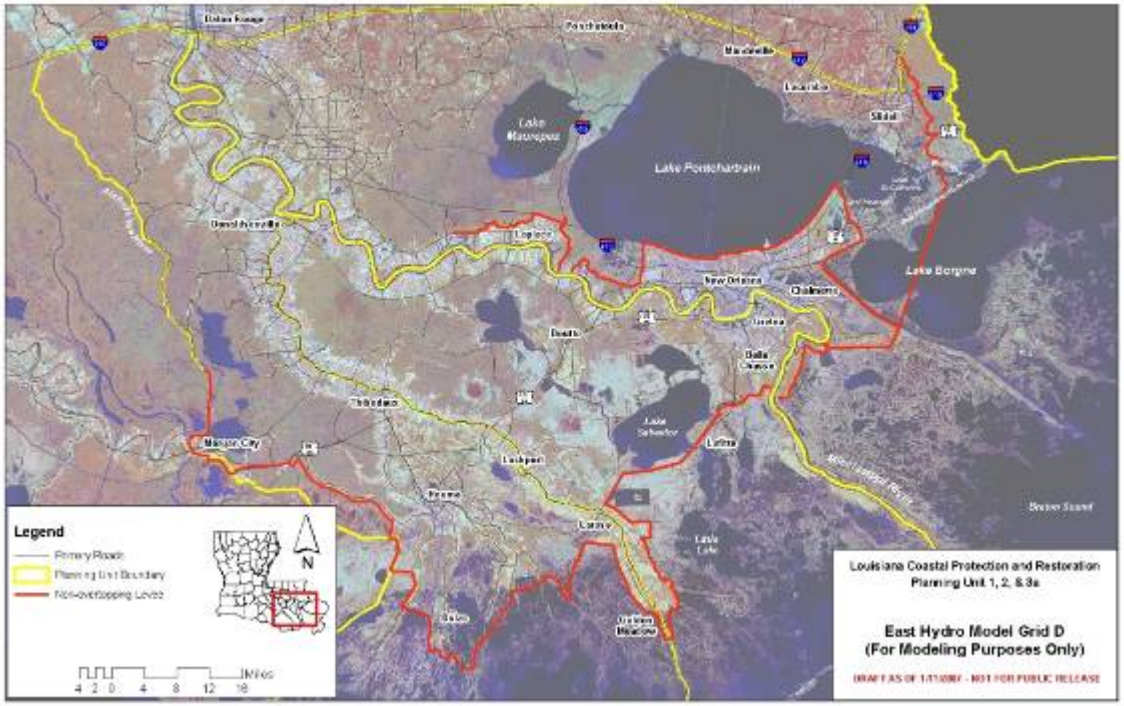

Figure 11.3.4.1-4. LACPR Model Grid D

Note that Grid A was not considered feasible and was eliminated due to the extreme height of the levees required to prevent overflow and the large increases in water levels in Lake Borgne and the Mississippi Sound.

Grid C contained the same non-overtopping levees but the gated control structures proposed for the Chef and Rigolets passes were removed from the grid so that the passes were left open during the hurricane simulation. The plan calling for removal of the control structures was suggested as an environmental plan by the US Fish and Wildlife Service. It was found that the surge responses in and around Lake Pontchartrain for this grid were essentially the same as with the Base 2010 Grid which represents the authorized 100-year hurricane protection system. Therefore the Grid C plan was eliminated as not being effective.

Grid D involved a barrier at a different location compared to the other barrier plans. Results for Grid D were similar to those for Grid A in that there were significant lowering of water levels in Lake Pontchartrain but outside stages were increased due to the Grid D levee alignment having closer proximity to the Mississippi Gulf Coast. Therefore the Grid D plan was eliminated from further consideration. Elimination of the alternatives reflected in Grids A and D were based in part on cross-region influences of these alternatives.

The Grid B, the Lake Pontchartrain surge reduction plan, essentially follows the Grid A alignment and has similar closures at the tidal passes. The connecting levees in grid B were, however, set to a lower elevation so that the levee would function as a weir and the more intense or severe storm surges would overtop this system and enter the Lake Pontchartrain Basin. The Grid B plan also showed substantial reduction in surges in Lake Pontchartrain, however, it caused increases in water levels on the Lake Borgne side of the proposed alignment and the Mississippi Sound. Figures

11.3.4.1-5 through 11.3.4.1-7 show the increase in water levels on the outside of the Grid B Pontchartrain surge barrier structure for the 100, 400 and 1000 year frequency events. It should be noted that due to the limited time for conducting the LACPR work an optimization of the weir height for a proposed surge reduction plan was not done. However, the results suggest that adjustments to the weir height could lead to perhaps a more cost effective plan that maximizes risk reduction and minimizes costs over the entire Louisiana/Mississippi project area. Should a surge reduction plan move to the next phase of planning, then a comprehensive assessment of weir elevations will be performed to evaluate any impacts.

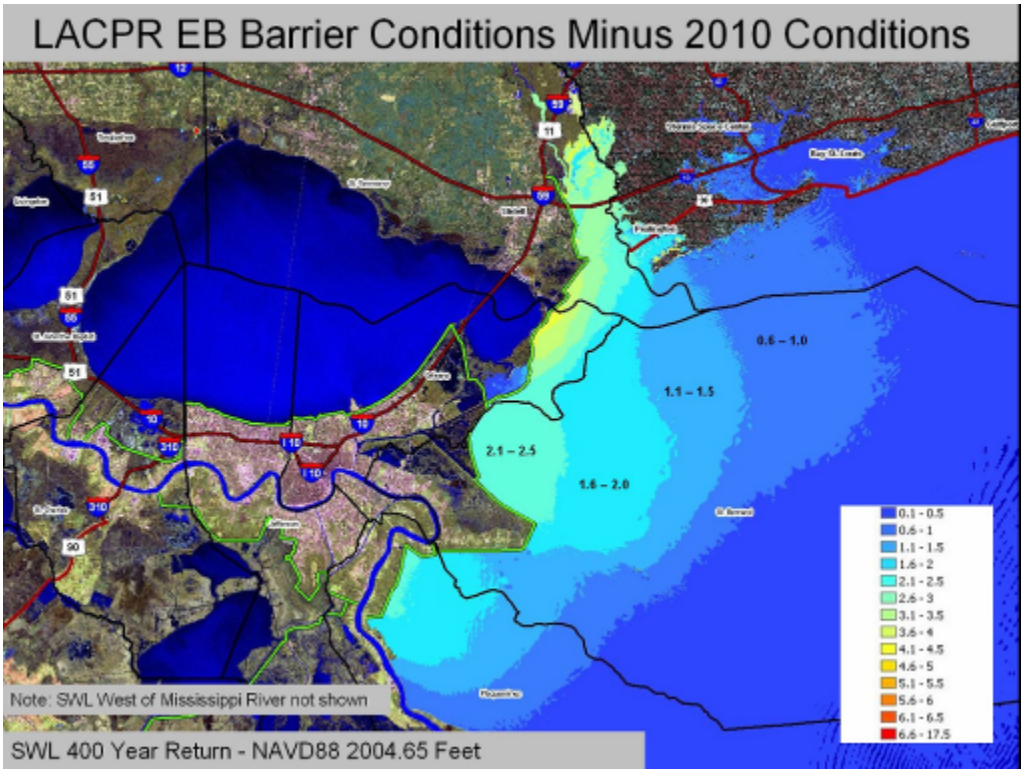

Figure 11.3.4.1-6. Regional-scale changes to 400-yr storm surge levels associated with the Grid B being considered in the LaCPR study.

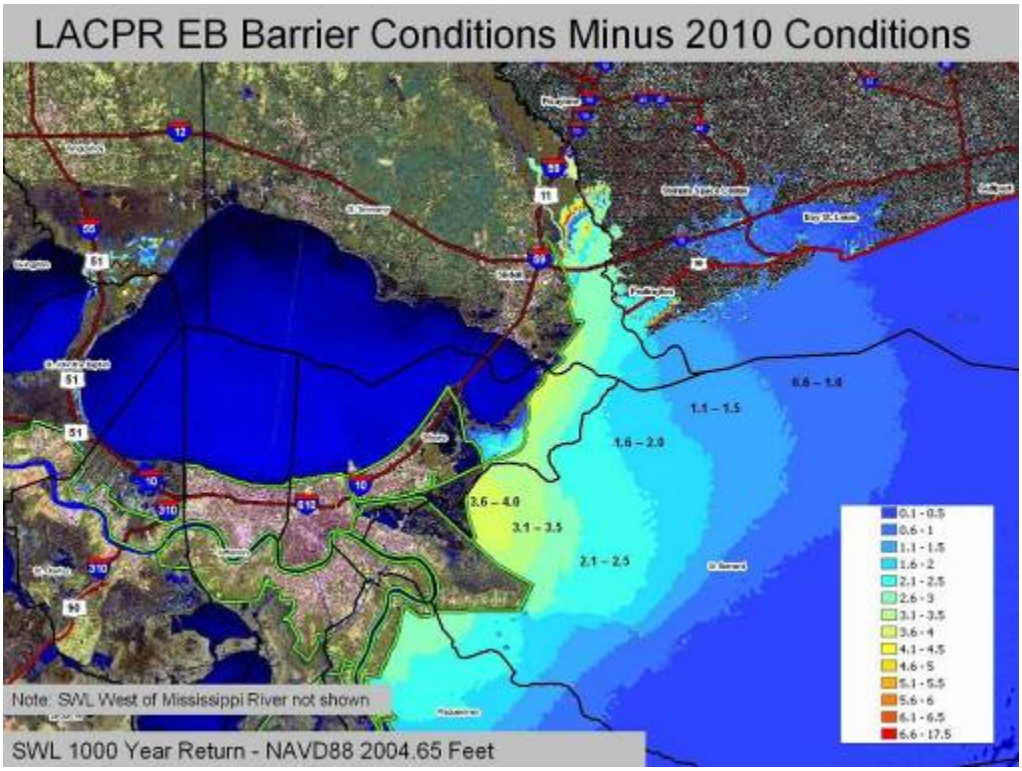

Figure 11.3.4.1-7. Regional-scale changes to 1000-yr storm surge levels associated with the Grid B being considered in the LaCPR study

11.4 Mississippi Barrier Island Restoration

The options being considered for MsCIP include potential projects involving the placement of sand in two of the planning zones, the Offshore Zone which includes the barrier islands of Mississippi, and the Coastal Zone which includes the mainland beaches of Mississippi. The barrier islands are mostly owned by the National Park Service (NPS) and are included in the Gulf Islands National Seashore. The mainland beaches are all man-made and stretch along about 40 miles of Mississippi's coast.

Immediately following Hurricane Katrina, the State of Mississippi proposed restoring the barrier islands back to a pre-Hurricane Camille condition with the concept that this would reduce storm surge on the mainland. Analysis of the land loss among the four islands indicated that from 1917 to 2006 (post-Katrina) over 1600 acres of the islands had been lost. To return the islands back to a 1917 footprint, approximately 66,000,000 cubic yards of sand of a quality similar in color, grain size, and roundness to the sand that currently comprises the barrier islands would be required. The NPS had concerns over the State's proposal because it directly contradicted their policy of letting nature take its course unless it was to restore by mitigating for the activities of man or to protect historical sites within Park boundaries.

Studies by the USGS and ERDC showed a continuing trend in erosion of the islands and that West and East Ship Island would probably be totally lost in the future. Loss of the islands would also be expected to drastically change the ecology of the estuary formed between the islands and the mainland. With all these considerations, the NPS and USACE formulated a plan (referred to as the NPS Plan) for the barrier islands that would help mitigate some of the loss at the islands due to frequent intense storms, relative sea level rise, and anthropogenic activities that may have resulted in a reduction in sand supply and prolong the existence of the islands. This plan includes direct placement of sand to fill a breach in Ship Island, commonly called Camille Cut, that has existed since Hurricane Camille, add sand to the littoral zone in two areas, and proposed changes in the disposal practices of littoral zone sediment removed from local navigation channels.

The proposed restoration of barrier islands has regional implications with respect to sediment sources that are required to achieve the restoration and may have impacts on storm surge in Louisiana. Landscape features such as barrier islands have the potential to reduce storm surge elevations. Land elevations greater than the storm surge elevation provide a physical barrier to the surge. Landscape features (e.g., ridges and barrier islands) even when below the surge elevation have the potential to create friction and slow the forward speed of the storm surge. The barrier islands serve as the first line of defense for the Mississippi coast.

The restoration of these islands is a large-scale project and regional influences on storm surge, waves and salinity/water quality should be considered. Any significant lengthening of a barrier island, or reductions to the width and cross-section of gaps between barrier islands has potential for altering tidal exchange and the regional salinity and water quality regimes.

11.4.1 Assessment Approach

The impact of barrier island restoration on storm surge at the mainland coast of both Mississippi and Louisiana was assessed with a sensitivity study of various barrier island configurations. Influences on salinity and water quality have not been examined. The sensitivity study is a primarily a qualitative assessment that provides valuable information on trends and relative performance but

one should be cautious about making quantitative assessments of surge reduction. The barrier island sensitivity study was conducted on a grid consistent with that applied for the IPET study. It should be noted that the analysis does not consider the morphologic changes to the barrier islands caused by erosion that occur during a storms passage. In these sensitivity tests, the barrier island cross-section was assumed to be invariant, which might be a reasonable assumption for the very high restored barrier island elevation that was considered in the sensitivity tests, but it would not be a good assumption for a low more natural Mississippi barrier island elevation. The analysis also does not consider changes in the structure of the hurricane itself due to landfall infilling phenomenon that may be influenced by landscape features such as barrier islands.

A suite of storms were identified for evaluating storm surge response to changes in barrier island configuration. The suite included two historical storms, Camille and Katrina, because those hurricanes did in fact make landfall on the Mississippi coast in 1969 and 2005, respectively. The storm simulated that would most effect the Louisiana coast was Hurricane Katrina. The barrier island configurations modeled for the historical Katrina were: 1) the existing Post-Katrina degraded condition (elevations ranging from approximately 2 to 6 ft (NAVD88 2004.65)); and 2) a Restored-High barrier island configuration with an extended (pre-Camille) footprint and an elevation of 20 ft NAVD88 2004.65. The Restored-High configuration represents a massive barrier island configuration that would be difficult to achieve; it was modeled for sensitivity purposes. The proposed restoration referred to as the NPS plan above is substantially less than the restoration modeled for sensitivity purposes and thus impacts on regional surges are expected to be much less than those reported below.

11.4.2 Preliminary Results

For the purposes of discussion and comparison, Figure 11.4.2-1 plots the difference in the Post-Katrina and Restored-High peak surge levels for simulations of Hurricane Katrina. There is a reduction in peak storm surge levels of 1.0 to 3.5 ft landward of the barrier islands and an increase in water level of less than 1 ft seaward of the barrier islands. The most significant change in peak storm surge is in the Pascagoula basin where levels are reduced 1 to 3 ft. Note that the impact of the restoration decreases moving east to west and there are smaller changes in the Louisiana area, on the order of tenths of feet. Surge reductions at the Mississippi mainland were approximately 20% in the Pascagoula area, 5 to 10% in the central part of the state, and less than 5% in Waveland. The increase in water level in Louisiana is less than 0.5 ft. The level of restoration recommended in the MsCIP study is much less than the Restored-High configuration and thus the impact on Louisiana is also expected to be less than the results presented in Figure 11.4.2-1. These preliminary results indicate that the restoration of the Mississippi barrier islands, as it is being proposed, is not likely to adversely impact storm surge levels in Louisiana. Once a barrier island restoration level is set, the specifics of the restored barrier island configuration for all islands can be used to modify the regional storm surge and wave model and simulated to more accurately estimate regional impacts. Impacts on waves and salinity should also be evaluated.

11.4.3 Regional Sediment Management Issues

The total quantity of sand required for NPS barrier island plan and mainland beach restoration is considerably less than what would be required for the total restoration of the islands, but still substantial. To fill the breach, the sand would have strict requirements on color, grain size, and roundness. In discussions with the USGS, a potential source of sand was identified at St. Bernard Shoals which is a submerged chain of barrier islands approximately 45 miles south of the Mississippi barrier islands. Both quality and quantity are assumed to be available, but further investigations are required to verify the source. Activity from oil and gas production in the local area must also be considered. Approximately 8,000,000 cubic yards of the high quality sand are needed to fill the

breach. An additional 10,000,000 cubic yards of sand is being proposed for placement into the littoral zone east of East Ship Island. This sand would not require the same quality as the direct beach placement, but would still have some physical characteristics that must be considered.

If additional studies are performed on these two measures, another potential source of sand would be investigated that would be much closer to the project site and would allow the beneficial reuse of dredged material. This further study would look at historical disposal areas for the Gulfport navigation channel that crosses through the littoral zone. The sediments that are removed from the channel during routine maintenance dredging have been placed in approved disposal areas that have been used for an extended period of time. While the material placed in these areas was not segregated by grain size, there may be substantial quantities of beach quality material that has potential for use at Ship Island, either for filling Camille Cut, adding to the littoral zone, or both. Reuse of the sediments from the disposal areas would follow Regional Sediment Management practices that promote keeping sediments in the littoral system and/or beneficial use of material that is removed during both new and maintenance dredging.

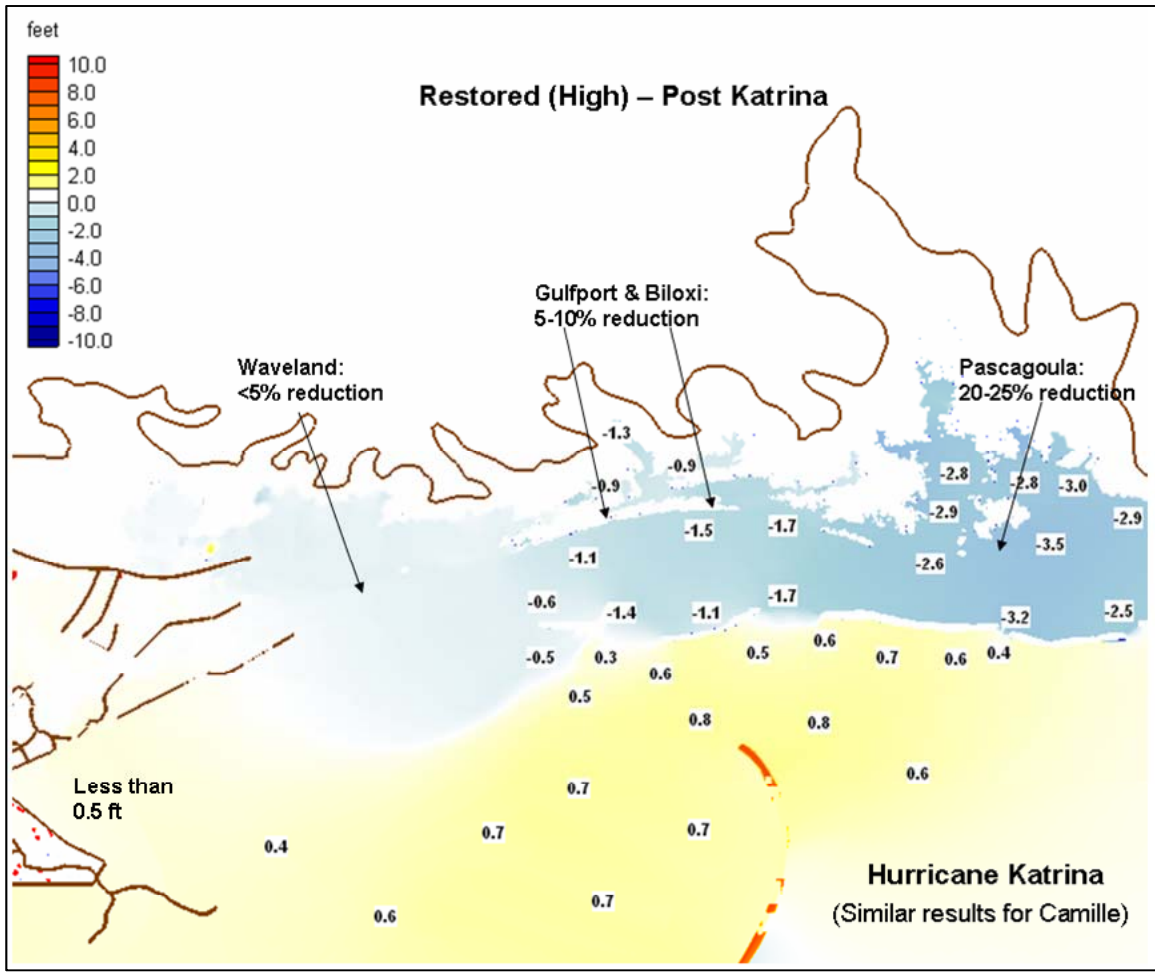

Figure 11.4.2-1. Difference in peak storm surge level (Restored-High – Post Katrina) for Hurricane Katrina

In this same local area, recent sediment transport studies have shown that westward sediment migration has been affected by the southward extension of the Mississippi River delta. This extension has cut off the littoral current and terminated the westward migration of sediments in the pass in the vicinity between Cat and West Ship Island. The fate of these sediments has not been determined, but there may be a large deposit of sand that could be used at Camille Cut or replaced in the littoral system.

Another segment of the Comprehensive Barrier Island Restoration Plan would be to add sand into the littoral zone east of Petit Bois Island. The source of this sand is proposed to be from the inland river system that flows into Mobile Bay provided that the sand is found to be compatible with sediment that exists within the littoral system. Prior to its use, these physical characteristics will be determined by sampling and testing of the inland sand for color, gradation, and particle shape (angularity). To maintain channel depths, sand is dredged from these rivers and placed in numerous upland disposal areas along the river. The lower Tombigbee River has several million cubic yards of sand stored along its banks that could potentially be used for the littoral zone placement based on the compatibility requirements mentioned above. Prior testing, including toxicity studies, has already been conducted on many of the sites. Due to the location of the disposal areas, this sand is being considered for use for the Petit Bois Island littoral zone placement. This source will provide the beneficial use of sand suitable for the littoral placement and at the same time provide additional dredged material storage capacity along the river system.

The placement of sand to fill Camille Cut and the two large littoral zone placements are planned as one-time events to restore some of the islands' land surface that may have been lost to erosion due to man's past activities or from mass erosion during storm events. This decision was based on an agreement with the NPS that allows them to mitigate ay damage from man's activities or to perform necessary means to preserve historic sites. This agreement has a positive aspect to MsCIP with the replacement of sand that has been lost from the littoral system. This sand addition will extend the life of the islands and the closure of Camille Cut will help maintain the boundaries of the estuary. It is understandably difficult to quantify either of these sand loss causes because the barrier islands themselves are dynamic systems that are undergoing constant change. The presence of two deepwater navigation channels that pass through the littoral zone have created artificial boundaries to the westward migration of the islands. The continued maintenance of these channels will require that sand and other sediments be removed, but under the guidelines of the Regional Sediment Management Practices, the sand removed from the channels will be returned to the littoral system.

The continuing study would evaluate future placement of maintenance material dredged from the Pascagoula Harbor Navigation Channel. It has been recommended that sand from the channel be placed down-drift in a newly designated disposal area located in the littoral zone near Sand Island. Much of the sand dredged in the past was placed down-drift, but was formed into a small island commonly called Sand Island. Sand Island has become a prime environmental resource vegetated with dune grasses that provide habitat to many types of shore birds. With no further sand additions, the sand within this island will probably return to the littoral system as wind, waves and currents erode the land mass.

Material removed from the Gulfport Channel has historically been placed in disposal areas south of the littoral zone. In keeping with the guidelines of the Regional Sediment Management Practices, new recommendations have been made to dispose of the material removed from the littoral zone segment of the channel. The channel at the western tip of West Ship Island is a trap for the migrating sand. It has been recommended to place the dredged sand in the littoral zone east of East Ship Island. This practice will allow the sand to nourish Ship Island and slow erosion of the land mass. How to best achieve this will be considered in the continuing study of the islands. Initial ideas include stockpiling the sand in selected areas so the material would be available in the future to relocate it into the littoral zone.

The mainland beaches that are in the Coastal Zone were created in the 1950s to provide protection to the seawalls along beachfront roads. Through time, the beaches have evolved into recreational use and environmental habitat. Some of the beaches have been periodically renourished by the local sponsors, primarily the counties. Options that have been studied under MsCIP have included the construction of dunes of various sizes and configurations. The sand for any dune construction will be purchased from any of numerous commercial sources along coastal Mississippi. This sand is typically of good quality and has been used in some of the past nourishments. There is also limited sand reserves available in approved borrow areas just offshore of the mainland beaches. This offshore sand is currently being used for a renourishment project in Harrison County.

Many of these same types of issues will be considered for alternatives that involve barrier island restoration in Louisiana. All of the sediment requirements discussed above must be considered in concert with any sand-source requirements that develop from the LaCPR study. Sediment management will be carried our in accordance with Regional Sediment Management practices.

11.5 LaCPR Wetland Restoration Plan

The LaCPR study is considering various restoration alternatives that will provide multiple benefits, particularly ecological benefits. Figure 11.5.1-1 shows an outline of the marsh restoration features being considered for eastern Louisiana. These features have the potential to reduce storm surge and wave action, and the regional implications of these projects will be considered. Landscape features such as wetlands also have the potential to create frictional resistance and affect storm surge even when vegetation is inundated by the storm surge.

11.5.1 Assessment Approach

The impact of wetland restoration on storm surge at the mainland coast of both Louisiana and Mississippi was assessed with a sensitivity study. The sensitivity study was primarily a qualitative assessment that provides valuable information on trends and relative performance but one should be cautious about making quantitative assessments of surge reduction. It should be noted that the analysis does not consider the morphologic and vegetation cover changes to the wetlands caused by erosion and/or damage to vegetation that occurs during a storm's passage. The analysis also does not consider changes in the structure of the hurricane itself due to landfall infilling phenomenon that may be influenced by landscape features such as wetlands.

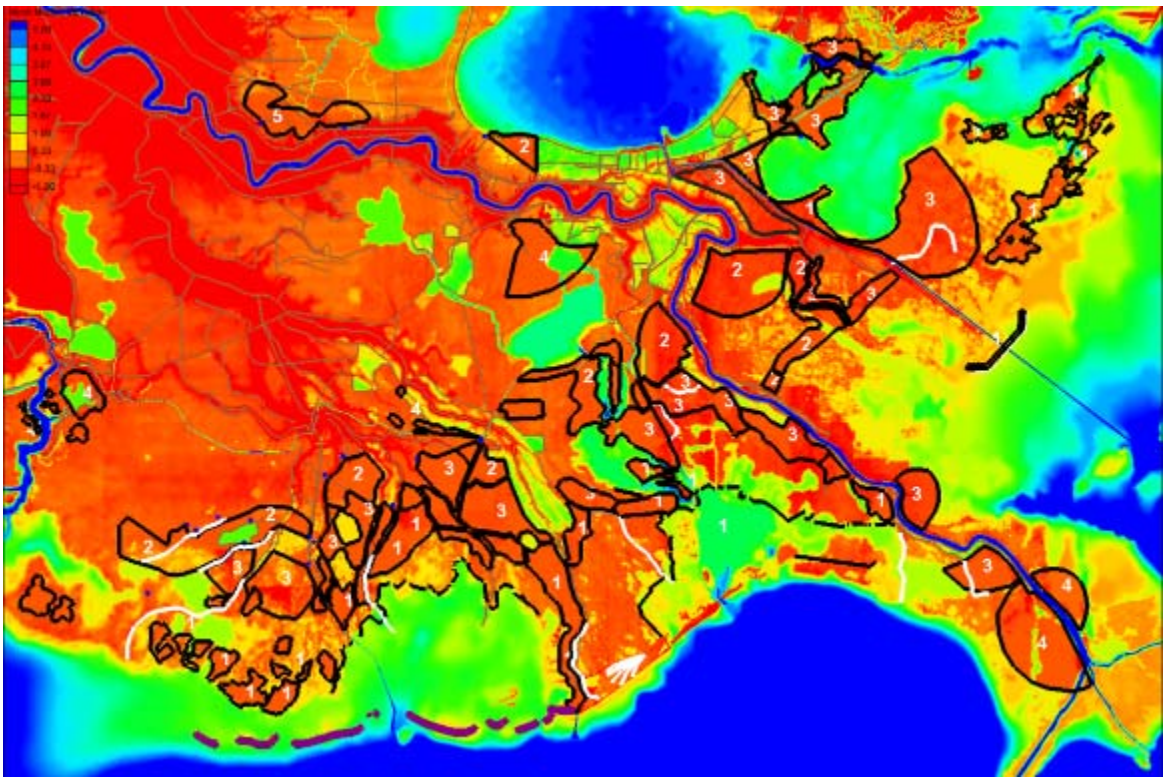

Figure 11.5.1-1. Outline of marsh restoration features. Marsh types are outlined as follows: 1 = saline, 2 = intermediate, 3 = brackish, 4 = fresh, 5 = cypress, white lines = ridges, purple = shrub/scrub for barrier islands. Colors indicate topographic/bathymetric elevation.

The restoration features outlined in Figure 11.5.1-1 were represented in the regional storm surge and wave model through modifications to the bathymetry, Manning's n values, and directional roughness lengths. A suite of 24 hypothetical storms was simulated on the restored condition and maximum water elevations were compared to maximum water elevations for the base condition.

11.5.2 Preliminary Results

Figure 11.5.2-1 presents the difference in maximum water level between the restored marsh configuration and the base case for the suite of 24 storms simulated for the immediate metropolitan New Orleans area. Note that the scale uses the color white to denote areas where changes in peak surge level are between + 1 ft and -1 ft. The wetland restoration has less than 0.5 ft impact on surge levels in both Louisiana and Mississippi. Based on these preliminary results, wetland restoration activities in Louisiana are not expected to adversely affect storm surges in the Mississippi area.

In a general sense, the influence of wetland restoration activities on storm surge and waves will be local in nature and relatively small for the types and spatial-scale of wetland restoration that are being considered and proposed in both the LaCPR and MsCIP studies. Impacts on waves may be greater than impacts on storm surge, but they are expected to be more local and are not expected to have significant regional influences outside the local area. For example, the wetland restoration proposed in the MsCIP study is local, and will not have significant storm surge or wave influences in Louisiana.

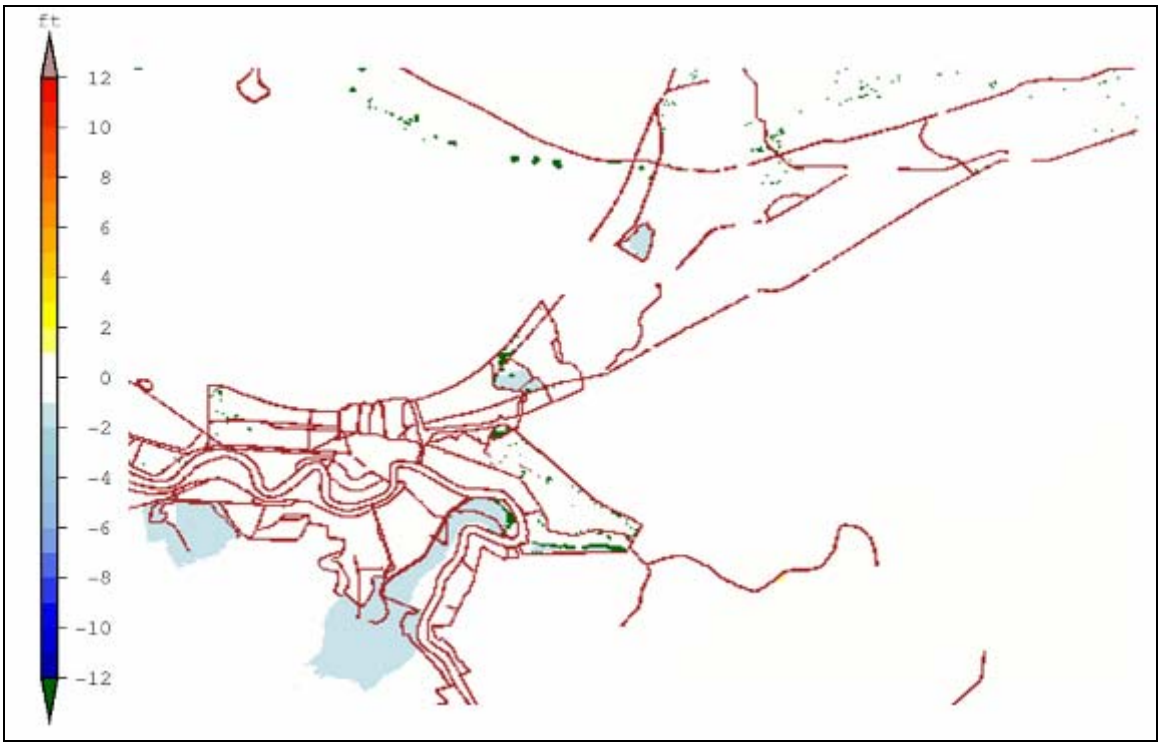

Figure 11.5.2-1. Difference in maximum surge level (ft) between the restored marsh configuration and the base case for the restored marsh storm suite

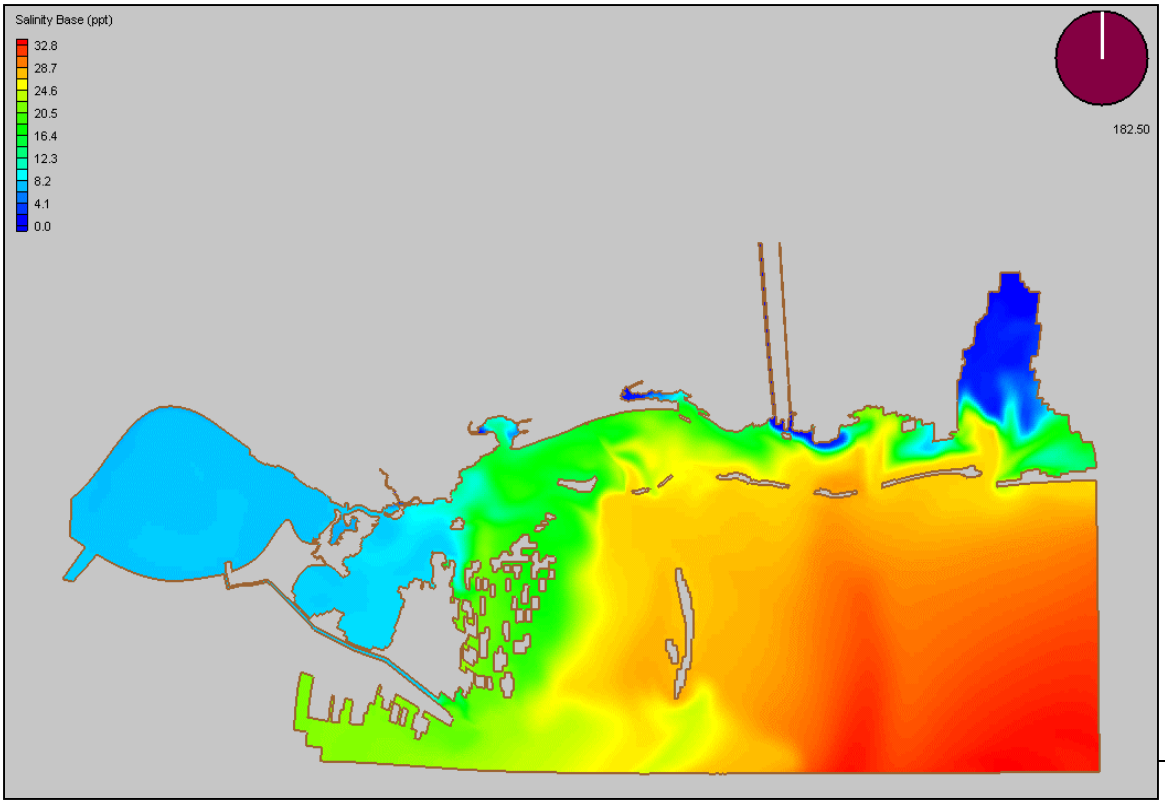
11.6 Mississippi River Diversions

The regional salinity and water quality model, WQM, has been applied to three alternative locations: (1) diversion of freshwater flow from the Mississippi River at Violet Marsh, (2) diversion of all of the Escatawpa River flow into Grand Bay, and (3) diversion of freshwater flow from the Mississippi River at Bonnet Carre' spillway. The purpose of these screening-level simulations was to examine whether or not freshwater diversions at these locations could produce reductions in salinity of a magnitude that are needed to achieve some of the objectives outlined previously for diversions.

11.6.1 Assessment Approach



A small range of potential diversion scenarios have been run and are reported in the appendices in the MsCIP report (Dortch et al. 2007). A limited number of operational schedules were considered. For example, the discharge from the Bonnet Carre' diversion was varied by month. The Violet Marsh scenario was a diversion with a constant flow of about 210 cu m/s (7500 cubic feet per second, cfs). The Escatawpa diversion scenario was the flow that occurred in the entire Escatawpa River during 1998. The hydrodynamic model was run with the same conditions as used for the base conditions used in the WQM calibrations for 1998 except that the additional freshwater flows were introduced. The WQM was applied for the period April through September 1998 using the same inputs as the final calibration run except for different hydrodynamic input and different boundary conditions for the diverted flow and associated concentrations of the flow.

11.6.2 Preliminary Results

As an example, the results from a simulated diversion of 7,500 cfs of Mississippi River water near Violet, Louisiana, are presented in Figure 11.6.2-1. The top panel of Figure 11.6.2-1 presents salinity results after 180 days for the baseline condition without a diversion; the bottom panel shows results after 180 days for the simulated Violet diversion. The results suggest that 180 days after initiation of the diversion, salinities were lowered in western Mississippi Sound sufficiently to warrant additional examination. However, at present, absolute salinity values predicted by the regional salinity/water quality model need to be improved to match calibration data. Further refinement of the model should correct this limitation and must be made to improve its potential to quantify the potential beneficial or deleterious effects on oysters and other coastal resources.

Preliminary efforts were made to relate the WQM model results to ecological communities by utilizing oysters as a "target species." Oysters not only support a commercial fishery but interact directly with local hydrodynamic conditions, affecting currents, flow conditions, and sedimentation patterns (Lenihan 1999). They filter large amounts of phytoplankton and detritus exerting a powerful influence on water quality, phytoplankton productivity, and nutrient cycling of estuaries (Dame 1996). Oyster reefs provide habitat for a wide range of other invertebrates present either on the oyster shell itself or in the interstices between shells. Oyster reefs also support numerous resident, transient, and juvenile fish and decapod species and may provide a refuge from predation and poor water quality conditions.

Oysters are sensitive to specific ranges of salinity; therefore, freshwater diversions have the potential to either enhance or threaten the resource. For instance, where the average salinity exceeds 15 ppt oysters often experience increased predation rates by oyster drills whereas young oysters are more susceptible to certain diseases at salinities greater than 9 ppt (Cake 1983; Chatry et al. 1983). Similarly, salinities averaging below 7.5 ppt can inhibit oyster growth and sexual maturation while salinities that persist for extended periods of time below 2 ppt can result in direct mortality (Sellers and Stanley 1984, 1986). The relationship between oyster productivity and river flow is a complex one and there does not appear to be a close link between oyster harvests and freshwater inflow (Turner 2006).

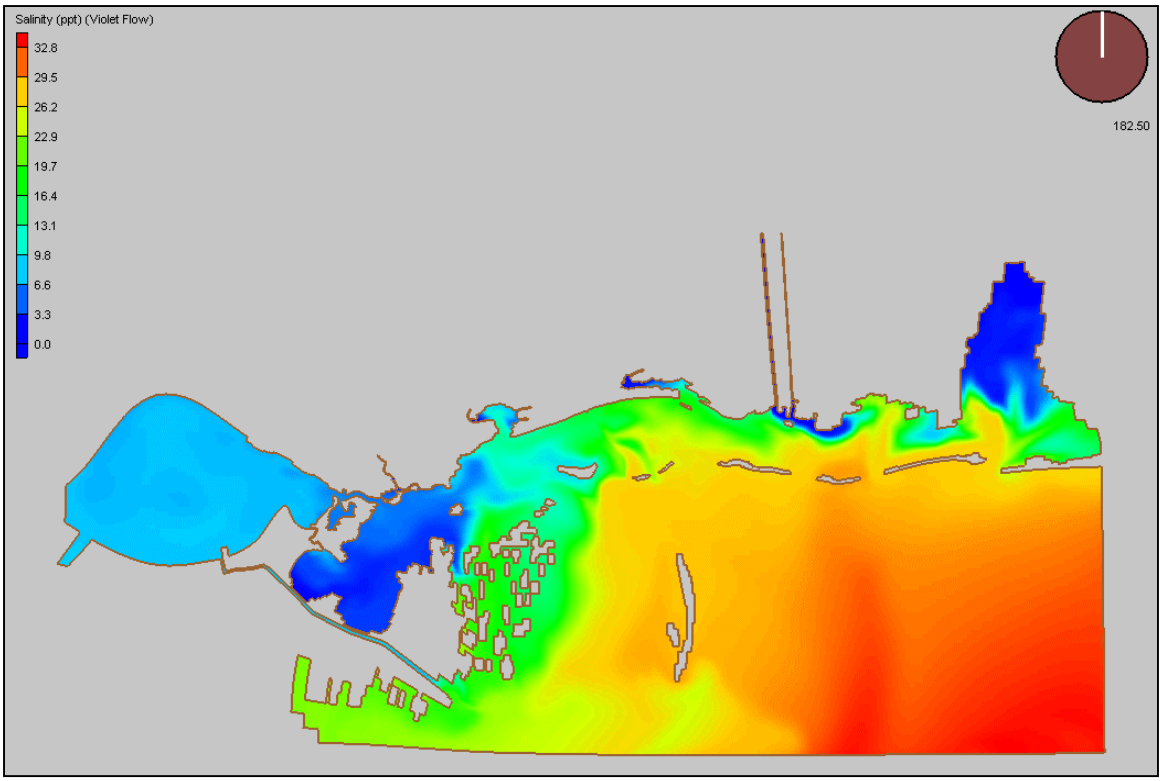


Figure 11.6.2-1. Baseline (upper panel) and projected with-diversion (lower panel) salinity values in parts per thousand (ppt) after 180 days. The royal blue color represents freshwater, while the red indicates sea water with salinity concentrations greater than 30 ppt.

To further refine the ecological concerns, during the summer and fall of 2007, MsCIP and ERDC convened a panel of representatives from the Nature Conservancy, Mississippi Department of Marine Resources, and the University of Southern Mississippi at the Gulf Coast Research Laboratory. The aim of the panel was to suggest simplistic ecological models that can be informed by results from the regional salinity/water quality model to identify diversion actions which might result in an improvement in oyster habitat quality. The panel identified several key attributes that need to be incorporated into the evaluation of freshwater diversion options. The first is that salinity averages should be as close as possible to the optimal range for oyster health and productivity. This is clearly of critical importance since the primary purpose for contemplating freshwater diversions is to improve habitat conditions for oysters. Second, a diversion should not result in extended periods of low salinity resulting in mortality or poor growth and reproduction. This consideration is particularly critical during times of high river flow or other extreme conditions. Third, a diversion should not unduly influence habitat conditions for other critical resources. Diversions that result in favorable conditions for oyster health may not be conductive to other equally important resources. For instance, most seagrasses do poorly at salinities less than 20 ppt. A diversion that results in excellent conditions over the prime commercial oyster beds but drives salinities below 20 ppt in the seagrass elsewhere would not be acceptable. Other important habitat requirements that should also be considered for seagrass health include light availability and nutrient concentrations.

During the autumn of 2007, several meetings with representatives from the States of Mississippi and Louisiana, non-governmental organizations such as the Lake Pontchartrain Foundation and the Environmental Defense Fund, various federal agencies, including US Fish and Wildlife Service, and representatives from both Mobile and New Orleans Districts have been held to discuss options, centering on details associated with a Violet Diversion. Additional work will be required to refine the

WQM regional model and apply it to examine the regional influences of proposed freshwater diversion projects on salinity, water quality and habitat.

11.7 PATH AHEAD

11.7.1 Continued LACPR-MSCIP Northern Gulf of Mexico Planning and Analysis

During the next steps in plan development in the LaCPR and MsCIP investigations beyond December 2007, the joint study teams will collaborate at a Northern Gulf of Mexico integrated systems scale. The purpose of this effort will be to identify common stakeholder agreement on the configuration, performance, and cost of alternatives with a goal of achieving no adverse impacts, levels of risk reduction, and coastal restoration in those plans. The LaCPR and MsCIP teams will hold joint meetings with stakeholders of the coastal areas in Louisiana and Mississippi during the winter-spring 2008 timeframe to accomplish this task, as follows:

- Explain the process on how the range of alternatives were initially developed in both projects for coastal restoration and risk reduction, as described in the December 2007 Technical Reports for LaCPR and MsCIP,
- Present the individual elements and integrated system configurations of the array of developed alternatives that were evaluated through these investigations,
- Describe the performance, costs, and unintended adverse consequences found through modeling simulations of these alternatives,
- Solicit the viewpoints of stakeholders for both studies in joint meeting sessions to identify consensus and differences of opinion on the makeup, performance, and costs of these alternatives,
- Interact with the stakeholders of both studies for screening, refinement, and/or re-formulation of alternatives from a Northern Gulf of Mexico integrated systems scale perspective,
- Conduct iterations of planning and analysis for identifying common agreement on the configuration, performance, and cost of alternatives for attaining no adverse impacts, risk reduction, and coastal restoration, and
- Describe requirements for further alternative plan development and analysis.

11.7.2 Regional Assessment Using Surge and Wave Modeling

In its current state, the regional storm surge and wave model is ready for use in examining regional influences and interactions that are created by MsCIP projects which are slated for construction in the near-term, and proposed LaCPR measures that remain in the final array of alternatives after the screening process. The alternatives proposed for construction in the MsCIP study and the most likely LaCPR alternatives will be evaluated using the regional storm surge and wave model to address regional influences of the proposed projects. Alternatives will be evaluated by the teams' storm surge and wave experts for the potential to produce significant regional influences. That evaluation will be reviewed and concurred upon by the external peer reviewers for both projects, and those alternatives will be assessed based upon regional storm surge and wave influences. All proposed projects/alternatives will be integrated into the regional storm surge and wave model and compared to results for the 2010 baseline case. By comparing the results to those obtained for the

baseline case, the MsCIP and LaCPR study teams can evaluate the regional influence of the proposed alternative(s).

Together, the MsCIP and LaCPR study teams, along with key stakeholder representatives, will evaluate the issue of regional storm surge and wave influences and assess whether or not there is a significant regional influence, and if so jointly decide whether any additional risk is acceptable, whether the project(s) must be modified to lessen the increased risk, or whether the project(s) need to be reformulated.

11.7.3 Regional Impact of the Lake Pontchartrain Surge Barrier

Analysis of storm surge barriers across Lake Pontchartrain indicates that a barrier can lead to significant undesirable increases in storm surge levels along the coast of Mississippi areas of southeast Louisiana. The increased surge levels are of great concern in light of the fact that coastal flood protection levees, revetments, or seawalls are not being pursued for construction in western coastal Mississippi. Therefore, any regional increase in storm surge levels induced by a Lake Pontchartrain barrier place the population at greater risk in an area that is already at relatively high risk of hurricane-induced flooding compared to other regions of the Gulf.

Lake Pontchartrain barriers provide considerable surge reduction benefits to certain communities around Lake Pontchartrain. The design of a storm surge barrier has not been optimized. Additional studies will be undertaken to assess the benefits of a lower surge barrier, which would likely also reduce adverse regional influences of the barrier. The regional influence issue will be addressed in the same manner as outlined above. Any barrier plan which induces adverse impacts must be eliminated from further consideration or its impacts satisfactorily mitigated on a regional basis.

11.7.4 Regional Assessment Using Salinity/Water Quality Modeling

All alternatives that involve barrier island restoration (specifically, those involving significant changes to island footprint or length), large-scale wetland restoration, storm surge barriers, or large-scale levee/floodwall systems will be evaluated for regional influences on salinity, water quality and habitat. The hydrodynamic, water quality, and habitat experts from the MsCIP and LaCPR study teams, plus outside peer reviewers for both projects, will make the assessment of which alternatives should be considered and integrated into the regional WQM model for this assessment. As was the case for the regional storm surge and wave model, the WQM model will be applied to examine regional influences of the alternatives (which fall into the categories outlined above) proposed for construction in the MsCIP study and the most preferable alternatives that surface in the LaCPR study.

The MsCIP study also is recommending construction of a freshwater diversion at Violet, Louisiana. Results achieved to date show that diversion at Violet has potential to achieve the salinity reduction that is sought for the Lake Borgne and Biloxi Marsh region in order to meet some of the objectives for diversions. It is expected that a freshwater diversion into this region will also be among the alternatives that surface in the LaCPR study. The issue of freshwater diversion into this region will be examined further, maintaining a regional perspective and building upon the work done to date to examine the relative benefits of freshwater diversions at Violet and the Escatawpa River, and Bonne Carre' as another possible diversion. A diversion at Violet was included in the 2007 Water Resources Development Act. In addition, a diversion at Caernarvon, Louisiana also will be examined in this same regional context.

It is proposed that a bi-state group be formed to assess freshwater diversions into this particular region, with support from the Mobile and New Orleans Districts and the Mississippi Valley and South Atlantic Divisions. One of the first activities of this group will be to fully articulate the goals of the

potential diversions and to reconcile conflicts between these goals. Subsequent to this, potential, realistic, operational plans will be developed so that they can be evaluated using the regional WQM modeling framework.

Refinements of the WQM model are required and they will be initiated immediately. The existing model will be expanded to the south and refined with additional resolution to include possible diversions at Caernarvon, and be readied for use in making event, seasonal and long-term simulations. Salinity changes at a number of time scales are of interest. The WQM model will be validated through comparisons to existing measured salinity and water quality data in Lake Pontchartrain, Lake Borgne, Biloxi Marsh, and the vicinity of Caernarvon in order to increase confidence in model predictions and to be able to withstand the close technical scrutiny of the modeling that is done to inform decision-making regarding this highly sensitive issue.

These model improvements will allow for more accurately relating the water quality results to ecological concepts and interpretation, and enable questions and issues that have been raised regarding diversions (pros and cons) to be more thoroughly and accurately addressed. The WQM model should be linked to ecological tools to be able to test the impacts of precise operational discharge plans and seasonal influences on key ecological resources. Our current collaboration with Louisiana State University on the ecological integration will be continued and expanded to more fully include representation from Mississippi.

Once recommended diversions and operational plans for those diversions are defined, they will be integrated into the regional WQM model, along with all the other features that are proposed for construction in the MsCIP study and proposed in the LaCPR study which have possible regional influences on salinity water quality and habitat. The modified regional model will be applied and results will be compared to the 2010 baseline condition. Differences will be examined to assess the regional performance of alternatives and to assess regional influences from salinity, water quality and habitat perspectives.

If alternatives emerge in LaCPR for regions west of the Mississippi River that have the potential for regional salinity, water quality and habitat influences, work will commence to expand coverage of the WQM to cover the areas where influences are of concern. This will be a significant effort.

11.7.5 Recommendations for Research to Benefit Regional Modeling

Both the regional storm/surge and WQM models, and inferences made using the results from the WQM model to infer ecological response, have a number of areas of technical uncertainty in the model formulation and knowledge base for making interpretation and analysis. This uncertainty can only be reduced through research and development that is focused on improving model capability in the areas having the greatest uncertainty. The LCA Science and Technology program will focus on these areas of technical deficiency via collaborative research conducted by USACE, State of Louisiana, other federal agencies and the academic community.

The greatest uncertainty lies in inferences made regarding ecological response to changes in hydrodynamics, sediment loading, salinity, and water quality and how they contribute to the general process of marsh creation and ecological health. This will be one area of focused research and development. Wetland and barrier island restoration will have to be undertaken accepting the fact that adaptive management will be required. Not everything will respond as originally envisioned and planned. The system is extremely fragile and complex, and knowledge and data volume/quality are poor in a number of technical areas. There are ongoing difficult-to-predict-and-quantify long-term processes like subsidence and sea level rise that complicate matters and render accurate long-term predictions to be highly uncertain and suspect. Changes to wetland restoration practices will be required, and constantly improving regional models can help better inform the adaptive management

process and more accurately assess regional influences. The goal for the research and development should be reductions in the uncertainties inherit in forecasts and predictions of ecological response.

A second area for focused research will be the area of beneficial use of wetlands for storm surge and wave reduction. Considerable scientific knowledge gaps, and lack of data volume/quantity, exist in this area. Reliable use of wetlands for surge and wave reduction benefits will require increased understanding of the friction resistance and energy dissipation characteristics provided by a wide range of vegetation species, changes of resistance and energy dissipation with increasing degree of inundation, and response of the vegetation and surrounding wetlands to the destructive forces of wind and energetic waves at varying levels of inundation. The goal for the research and development should be reductions in the uncertainties inherit in forecasts and predictions of wetland influence on storm surge and waves.
